9

10   **Key Points:**

11   • Thermal fatigue is an active mechanical weathering process that drives boulder
12   exfoliation and breakdown on Bennu.
13   • Exfoliation is capable of ejecting centimeter-scale particles from the asteroid surface at
14   speeds of meters per second.
15   • This mechanism shows good agreement with particle ejection observations and is a viable
16   origin for Bennu's activity.

1 **Abstract**

2 Many boulders on (101955) Bennu, a near-Earth rubble pile asteroid, show signs of *in situ*
3 disaggregation and exfoliation, indicating that thermal fatigue plays an important role in its
4 landscape evolution. Observations of particle ejections from its surface also show it to be an active
5 asteroid, though the driving mechanism of these events is yet to be determined. Exfoliation has
6 been shown to mobilize disaggregated particles in terrestrial environments, suggesting that it may
7 be capable of ejecting material from Bennu's surface. We investigate the efficacy of thermal
8 fatigue and exfoliation as a mechanism for generating asteroid activity by performing finite
9 element modeling of stress fields induced in boulders from diurnal cycling. We develop a model
10 to predict the spacing of exfoliation fractures, and the number and speed of particles that may be
11 ejected during exfoliation events. We find that crack spacing ranges from ~1 mm to 10 cm and
12 disaggregated particles have ejection speeds up to ~2 m/s. Exfoliation events are most likely to
13 occur in the late afternoon, though lower energy ejection events may also result from nighttime
14 stress fields. These predictions are consistent with observed ejection events at Bennu and indicate
15 that thermal fatigue is a viable mechanism for driving asteroid activity. Crack propagation rates
16 and ejection speeds are greatest at perihelion when the diurnal temperature variation is largest,
17 suggesting that events should be more energetic and more frequent when closer to the Sun. Annual
18 thermal stresses that arise in large boulders during perihelion approach may enhance this trend.
19

20 **Plain Language Summary**

21 Soon after its rendezvous with the asteroid Bennu, the OSIRIS-REx spacecraft observed the
22 asteroid to be ejecting tiny particles of material. Bennu is a rubble-pile asteroid covered in rocks
23 and boulders of varying size. Many of these boulders show evidence of exfoliation, a process
24 where thin layers of material are shed from their surfaces. Exfoliation is one consequence of
25 thermal fatigue, which is the slow and progressive lengthening of cracks caused by the daily
26 variation in boulder temperature from exposure to the Sun. Here we explore how the process of
27 exfoliation could lead to the ejection of particles from the asteroid surface and compare our results
28 to the spacecraft observations of the ejection events. The model we develop is used to predict the
29 timing, number, and speeds of particles that may be ejected during thermal fracturing events. Our
30 result suggests that particles ejected from boulder surfaces during exfoliation can have speeds up
31 to ~2 m/s and are most likely occur when Bennu is closest to the Sun and during the late afternoon,
32 consistent with spacecraft observations.

1 Introduction

Observations of 101955 Bennu by the Origins, Spectral Interpretation, Resource Identification, and Security–Regolith Explorer (OSIRIS-REx) spacecraft have revealed a rough surface dominated by boulders with diverse morphologies and textures [*DellaGiustina and Emery et al.*, 2019; *Walsh et al.*, 2019; *Lauretta and DellaGiustina et al.,* 2019]. Signs of *in situ* degradation, mass movement, craters, and cracks hint that its surface is influenced by a variety of weathering, impact, and other processes [*Barnouin et al.*, 2019; *DellaGiustina and Emery et al.*, 2019; *Walsh et al.*, 2019]. Although dedicated searches for asteroid activity during the spacecraft's approach detected none [*Hergenrother et al.,* 2019], navigational images taken from orbit have also unexpectedly revealed that Bennu has an active surface [*Lauretta and Hergenrother et al.*, 2019] Multiple particle ejection events were observed starting in January 2019, shortly after the OSIRIS-REx spacecraft entered orbit. The two largest events occurred near asteroid perihelion, with numerous smaller events observed in the months following [*Lauretta and Hergenrother*, 2019; *Hergenrother et al., in review this collection*; *Leonard et al., in review with Earth and Space Science; Pelgrift et al., in review with Earth and Space Science*]. Several mechanisms have been suggested to drive these ejection events, including electrostatic lofting of particles [*Hartzell, in review this collection]*, meteoroid impacts [*Bottke, in review this collection]*, phyllosilicate dehydration, and thermal fracturing [*Lauretta and Hergenrother*, 2019]. This work focuses on the lattermost mechanism, exploring its efficacy on Bennu's surface and possible contribution to ejection events.

Many of Bennu's boulders show signs of exfoliation, the flaking and disaggregation of thin layers of surface material. Recent work by Molaro et al. [*in review with Nature Communications*] has demonstrated that these features on Bennu result from thermal fatigue, a subcritical crack growth process driven by diurnal thermal cycling [*Holzhausen*, 1989]. Previously, we lacked morphological evidence that fatigue could operate airless body surfaces, though numerous studies had hypothesized that it may play an important role [*Dombard et al.*, 2010; *Jewitt and Li*, 2010; *Delbo et al.*, 2014]. Although models [*Molaro et al.*, 2015; *Hazeli et al.*, 2018; *Mir et al.*, 2019] and laboratory investigations [*Thirumalai and Demou*, 1970; *Levi*, 1973; *Delbo et al.*, 2014] have provided valuable insight into its nature, the opportunity to study fatigue *in situ* on Bennu's surface provides new pathways for understanding how it drives landscape evolution and interacts with other surface processes such as micrometeoroid impacts. In terrestrial environments, fatigue often works in synergy with various chemical and biogenic weathering processes to drive boulder breakdown [*Waragai*, 1998; *McFadden et al.*, 2005; *Fletcher et al.*, 2006; *Eppes et al.*, 2010; *Eppes and Keanini*, 2017]. At very large scales, exfoliation of terrestrial rock domes is thought to result from landscape-scale tectonic stresses [*Martel*, 2011; *Collins and Stock*, 2016; *Martel*, 2017], with diurnal thermal cycling playing a strong role in the disaggregation of surface layers [*Collins et al.*, 2018]. Field observations show that dome exfoliation can occur in dramatic and spontaneous episodes, where crack extension causes exfoliation layers to pop up off the surface, releasing audible acoustic waves and mobilizing loose particles [*Collins et al.*, 2018]. Although the tectonic factors at play are thought to add significant energy to such events, this leads to the question of whether fatigue-driven, boulder-scale exfoliation may be capable of ejecting surface material in a microgravity environment where less energy is needed to mobilize material. If so, this has important implications for our understanding of asteroid geology and the active asteroid population.

Here we investigate the efficacy of thermal fatigue and exfoliation as a mechanism for generating asteroid activity. We perform finite element modeling of stress fields induced in

1   boulders from diurnal thermal cycling to assess the extent to which different thermal fracture
2   processes may operate. We focus primarily on thermal fatigue, exploring how it may drive the
3   development of fractures and boulder morphologies observed on the asteroid surface. Similar
4   studies have been conducted for terrestrial [*Eppes et al.*, 2016] and lunar [*Molaro et al.*, 2017]
5   boulders and to develop scaling laws for estimating stress magnitudes and resurfacing rates on
6   arbitrary asteroid surfaces [*El Mir et al.*, 2019; *Graves et al., 2019*], though these studies vary in
7   approach and boulder properties. This work provides new insight into how fatigue operates on
8   carbonaceous chondrite materials and the differences between its efficacy and expression on the
9   Moon versus on asteroid surfaces. We use the simulation results to develop a model to predict the
10 spacing of exfoliation fractures and the size and speed of particles that may be ejected from
11 Bennu's surface during an exfoliation event. Finally, we compare our results to observational
12 constraints from Bennu's particle ejection events to assess the likelihood that thermal fatigue is
13 their driving mechanism.
14

15 **2 Finite Element Model**

16 Following Molaro et al. [2017], we used COMSOL Multiphysics to perform three dimensional
17 finite element modeling to simulate stress fields in boulders on Bennu's surface. We modeled
18 spherical boulders embedded halfway in a volume of unconsolidated regolith. The sides of the
19 regolith volume were fixed with respect to displacement and periodic with respect to temperature.
20 The bottom boundary was also spatially fixed with a heat flux boundary condition of zero,
21 appropriate for a small body with negligible radiogenic heating. The boulder and regolith surfaces
22 are free to move in response to thermal forcing, as is the shared "thermal contact" layer between
23 them. The heat transfer across this boundary is given by $(k_{eff}/\delta)\Delta T$, where k_{eff} is the effective
24 thermal conductivity of the two materials and δ is the thickness of the boundary layer (assumed to
25 be 10^{-6} m). See Molaro et al. [2017] for additional information about the model and its sensitivity
26 to these parameters, which have a negligible impact on our results. A discussion of the influence
27 of boulder shape and surface roughness on our results is included in Section 3.4 and Appendix B.
28   Incident solar radiation was applied to the surface by defining a blackbody at infinite
29 distance with a flux of 1361 W/m², and its position and value were adjusted using time-dependent
30 solar distance and xyz coordinates computed using the NAIF (Navigation and Ancillary
31 Information Facility) SPICE (spacecraft, planet, instrument, constants, and events) Toolkit. The
32 coordinates were computed at a latitude and longitude of 0 over one solar day at Bennu's
33 perihelion. The heat flux is also adjusted based on the local surface slope and orientation of each
34 mesh element, as well as the effects of radiation scattered and exchanged with surrounding mesh
35 elements. We also applied a correction to account for the size of the solar disc during a local sunrise
36 or sunset by scaling the incident flux linearly with the portion of the solar disc visible above the
37 local horizon.
38   Measurements of the thermal and mechanical properties of carbonaceous chondrite
39 materials are limited in the literature. Although the thermal properties of Bennu's surface can be
40 inferred from its thermal inertia within some parameter space, an object's thermal and mechanical
41 properties are physically interwined and the latter are not constrained by spacecraft measurements.
42 For this reason, it is most physically realistic to simulate boulders that have the properties of a
43 terrrestrial analog material, for which both thermal and corresponding mechanical properties are
44 well constrained. The closest spectral match to Bennu's surface is CM carbonaceous chondrites
45 [*Hamilton et al.*, 2019], which are composed primarily of serpentine-group phyllosilicates, so we

1 assumed the boulders to have the bulk properties of terrestrial serpentinite. We simulated "dense"
2 and "porous" boulders, with properties (Table 1) representative of those at each end of
3 serpentinite's range of porosities (10 to 35%, respectively). The higher porosity is midrange
4 between measurements of CM chondrite porosity (23%) [*Macke et al.*, 2011] and Bennu's bulk
5 porosity (50%) [*Barnouin et al.*, 2019], and is also consistent with the porosity of CI chondrites
6 (35%) [*Macke et al.*, 2011], another possible Bennu analog. The thermal conductivity of the porous
7 boulders is consistent with that measured for CM chondrite meteorites [*Opeil et al.*, 2010], as well
8 as with the linear decrease expected for serpentinite with increased porosity [*Horai*, 2012]. All
9 materials (including the regolith, discussed below) have a temperature-dependent heat capacity
10 (c_p) following Ledlow et al. [1992] and an albedo of 0.044 [*DellaGiustina et al.*, 2019;
11 *Hergenrother et al.,* 2019].
12   Using the material properties in Table 1, Bennu's rotation period (P) of 4.288 hours, and a
13 c_p of 755 J/kg K at 300 K, we obtain a diurnal thermal skin depth ($\sqrt{2kP/(\pi\rho c_p)}$) of 11 and 6 cm
14 for dense and porous boulders, respectively. These are deeper than the 0.8 to 3 cm derived from
15 the measured thermal inertia of Bennu's surface (~350 J/m^2 K s$^{\frac{1}{2}}$ [*DellaGiustina and Emery et al.*,
16 2019]). This discrepancy is a result of the fact that the thermal inertia ($\sqrt{k\rho c_p}$) of our analog
17 materials is higher than that of Bennu's surface, with values of 2177 and 827 J/m^2 K s$^{\frac{1}{2}}$ for dense
18 and porous boulders, respectively. This indicates that one or more of the thermal properties that
19 we use do not match Bennu's real surface materials, or that the measured thermal inertia reflects
20 the presence of fines (centimeter-sized particles or smaller) on Bennu's surface, which serve to
21 lower its effective thermal inertia relative to solid rock. It is also possible that damage
22 accumulation from fatigue or other weathering mechanisms may lower the porosity of boulder
23 surfaces relative to their interiors. The magnitude of induced stresses is controlled primarily by the
24 boulder mechanical properties [*Molaro et al.*, 2017], and thus this discrepancy has a negligible
25 effect on our results. A decrease in boulder thermal conductivity to better match Bennu's thermal
26 inertia without a corresponding decrease in Young's modulus would actually result in a slight
27 increase in stress magnitudes. A more important effect is that it would decrease the depth to which
28 exfoliating stresses reach, but this would not change our results at the order of magnitude level.
29   We can address the discrepancy in part by ensuring that the effective thermal inertia of the
30 combined regolith and boulder surfaces matches that of Bennu, and therefore that the temperatures
31 they experience are a realistic approximation of the asteroid's thermal environment. The density
32 of the regolith was assumed to be equal to that of lunar regolith, and its thermal conductivity was
33 adjusted such that the thermal inertia of the model geometry's visible surface area was 350 J/m^2 K
34 s$^{\frac{1}{2}}$ [*DellaGiustina and Emery et al.*, 2019]. This yielded conductivity values of 0.076 W/m K and
35 0.125W/m K for the regolith surrounding dense and porous boulders, respectively. Although the
36 lunar surface is not a good analog for Bennu in the context of surface roughness or density,
37 approximating the material surrounding the boulder as unconsolidated fines serves to increase
38 computational efficiency. The regolith's thermal properties are only important in that they
39 thermally insulate the boulder's lower half and provide physical boundaries in the simulation.
40 Because unconsolidated materials have low elastic moduli and thermal expansion coefficients, this
41 assumption also eliminates the possibility of any confining pressures or artificial stresses at the
42 thermal contact boundary that could alter the stress field in unrealistic ways. The nature of the
43 stress field in a boulder that thermally interacts with other nearby boulders or that has less
44 thermally insulated volume would not differ qualitatively from our results, and the quantitative
45 sensitivity of the stress magnitude to these effects is lower than to the boulder's mechanical
46 properties [*Molaro et al.*, 2017].

2
3

4   To calculate the temperature and stress fields within the boulders, we then solve the
5 localized heat balance equation for heat transfer in solids over time using an implicit solver and
6 dynamic time step. This is given by:

7

8
$$c_p\rho\left(\frac{dT}{dt} + u \cdot \nabla T\right) + \nabla \cdot Q = -\alpha T : \left(\frac{dT}{dt} + u_{trans} \cdot \nabla S\right) \qquad (1)$$

9

10 where Q is the conductive and radiative heat flux, u_{trans} is the velocity vector of translational
11 motion, α is the coefficient of thermal expansion, and S is the second Piola-Kirchhoff stress tensor.
12 The (:) operator is the double dot product. The right side of Equation 1 accounts for thermoelastic
13 damping, where the displacement (u) is a function of the Cauchy stress tensor, which relates to
14 elastic and thermal strain. See Molaro et al. [2017] for additional details on the model, including
15 sensitivity to model settings and material properties. The value of stress that we report is the
16 maximum principal stress, where positive stress is tensile. Stress uncertainties are described in
17 Appendix A.

18

19 **3 Model Results and Discussion**

20   The stress fields induced in boulders undergoing thermal cycling are spatially and
21 temporally complex. Tensile stresses arise in different parts of the boulders at different times of
22 day, and their orientation leads to crack propagation in different directions. Although all of these
23 stresses are part of the boulder's continuous mechanical response to heating, it is helpful to think
24 about certain effects as separate stress fields that each contribute differently to the overall
25 morphological evolution of boulder shapes and sizes over time. Molaro et al. [2017] illustrated the
26 three primary stress fields (Figure 1) induced by diurnal cycling in their simulations of lunar
27 boulders: deep interior stresses that drive through-going fractures, near-surface or exfoliation
28 stresses that drive surface-parallel fractures, and surface stresses that drive surface-perpendicular
Figure 1. Stress field in a cross section of a 2 m boulder at mid-morning, showing developing exfoliation stresses on the boulder's east face and surface stresses on its west face. Lines show the direction of stress (σ) and cracking (c). The dashed line shows the approximate exfoliation depth, and the dot is the approximate location maximum of the exfoliation stress field. Black regions have negative (compressional) stress. The Sun moves from right to left in the plane of the image.

fractures. We will discuss each of these effects in the context of Bennu's boulders and relate the simulations to observations of the surface. Parameters from the simulations will also feed into the crack spacing and particle ejection model discussed in the following section, which we will relate to the observed particle ejection events at Bennu [*Lauretta and Hergenrother et al.*, 2019; *Leonard et al.*, *in review with Earth and Space Science*].

3.1 Stress Magnitudes

The magnitude of thermally induced stress is directly proportional to the amplitude of temperature variation experienced by an object, which is controlled by its thermal and mechanical properties and the thermal environment. Stresses are highest in dense, brittle materials that do not easily deform in response to thermal forcing, and each stress field varies differently with boulder size (Figure 2). Stresses in boulders that are more porous owing to compositional differences or damage accumulation are weaker in magnitude, though their orientations remain unchanged. Surface stresses range from ~2 to 5 MPa, increasing with boulder diameter as a result of decreased surface curvature. Exfoliation and deep interior stresses are both controlled by the size of the boulder with respect to the diurnal skin depth. They peak at a diameter of ~5× the skin depth and decrease in larger boulders, ranging from ~0.4 to 3 MPa and ~0.2 to 2 MPa for exfoliation and interior stresses, respectively. These are comparable to the tensile strengths of our terrestrial serpentinite analog (0.5 to 5 MPa) [*Burk*, 1964; *Altindag et al.*, 2010] and similar soft, anisotropic materials such as limestone and shale (1 to 12 MPa) [*Sanio*, 1985; *Chen et al.*, 1998]. Even the weakest stresses are comparable to the estimated tensile strength of boulders on (162173) Ryugu (0.2 MPa) [*Grott et al.*, 2019], which is also a carbonaceous asteroid. Such conditions make it plausible for thermal fracture processes to be active at Bennu, and reinforces the finding that thermal fatigue drives exfoliation of Bennu's boulders [*Molaro, in review with Nature Communications*].

As a subcritical crack growth process, thermal fatigue only requires stress of ~10% of the material's tensile strength to occur in terrestrial environments [*Lawn*, 1993]. On Earth, it is typically aided by stress corrosion and other synergistic chemical weathering mechanisms
Figure 2. Peak surface (solid circle), exfoliating (open circle), and deep interior (asterisks) stresses in dense (left) and porous (right) boulders of varying diameter. The error bars represent uncertainty due to mesh size and location of peak stress (Appendix A).

[*Fletcher et al.*, 2006; *Aldred et al.*, 2016; *Eppes and Keanini*, 2017], and studies have shown that crack propagation in vacuum can be harder to achieve [*Krokosky and Husak*, 1968; *Thirumalai and Demou*, 1970; *Kranz*, 1979]. This makes it unclear if the same rule still applies or if a higher stress magnitude is needed to drive fatigue in asteroid environments. Better constraints on material strengths and fatigue thresholds will come as researchers observe and map more thermal fracture features on the asteroid, and through analysis of the returned samples. Other fracture processes such as thermal shock or contraction cracking can only occur if the material's full strength is overcome. Such processes could have played a role in Bennu's past when it migrated to near-Earth space, as laboratory work shows that exposure of material to a new maximum temperature results in a rapid (geologically instantaneous) burst of crack growth arising from the expansion and reorientation of mineral grains as they re-normalize to a new thermal cycle [*Thirumalai and Demou*, 1970; *Richter and Simmons*, 1974]. Fracture and material ejection from thermal spallation is also known to occur when boulder surfaces heat very rapidly (e.g., in a forest fire) [*Walsh and Lomov*, 2013]. It is not clear that there is enough energy to produce these types of behavior at Bennu. If so, they would be most likely to occur on boulders and boulder faces that are freshly exposed by mass movement or impact processes, or as a result of specular reflection or other effects that may enhance heating in localized areas. Exploration of such effects is beyond the scope of this paper, and therefore we will focus the remainder of our discussion primarily on thermal fatigue.

The magnitude of diurnal stresses decreases with increasing solar distance for a body with a given rotation rate due to the decrease in incident solar radiation. The average temperature of a 1 m boulder on Bennu decreases by ~50 K at aphelion (1.36 au) relative to perihelion (0.89 au), resulting in a decrease in the magnitude of peak stresses by ~50%. As a result, the rate of fatigue varies throughout its orbit, which adds complexity to understanding fracture development timescales and estimating breakdown rates. For a 1 m boulder, variation in stress with solar distance follows an approximate power law relationship with an exponent of –1.2. One might expect a similar trend with lower stresses induced in boulders at higher latitudes, which does occur for flat surfaces. However, highly sloped boulder faces oriented towards the equator still experience large temperature changes [*Molaro and Byrne*, 2012] and therefore are equally subject

to thermal fatigue as boulders at the equator. Rozitis et al. [*in review this collection*] simulated surface temperatures using a global shape model of Bennu and found that high (relative) diurnal temperature amplitudes occur at all latitudes due to its large-scale surface roughness. However, a trend with latitude would be expected on an asteroid whose boulders are much smaller in scale relative to the body's surface curvature. Compared to the equatorial case, the orientation of stress fields in boulders at higher and lower latitudes is rotated relative to the direction of the Sun's path (Section 3.4 and Appendix B).

Overall, these stresses have lower absolute magnitudes than those reported by Molaro et al. [2017] for lunar boulders because the diurnal temperature variation on Bennu is smaller and the boulders have lower Young's moduli. However, stresses in lunar boulders are an order of magnitude lower than their presumed tensile strength, making it less clear whether the stress threshold to drive thermal fatigue on the Moon is met. Further, the lunar cycling rate is only 12 cycles/year compared to Bennu's 10^3 cycles/year. Combined, these two factors suggest that thermal fatigue on the Moon, if it occurs, happens more slowly than on Bennu, which may help to explain the lack of evidence observed in its boulder morphologies [*Basilevsky et al.*, 2015]. On any given body, the fatigue efficacy will be controlled by composition, rotation period, and solar distance [*Molaro et al.,* 2017]. As discussed by Molaro et al. [*in review with Nature Communications*], the boulder composition and interactions between fatigue and rock fabrics may also play a role in the expression of fatigue on Bennu, making it more susceptible to developing features like exfoliation that can be distinguished from impact damage. One notable difference from the lunar trend of stress magnitude with boulder size is Bennu's lack of a local stress maximum for boulders ~8× the diurnal thermal skin depth. In lunar boulders, this local maximum is distinct from where the peak exfoliation stresses occur (~11× the skin depth) and is attributed to the control of strong heat flux out of boulder surfaces at sunset. Molaro et al. [2017] predicted that fatigue should cause breakdown of boulders in this size range to be most efficient, evidence for which is apparent in the lunar boulder size-frequency distribution [*Li et al.*, 2017]. This effect is not present on Bennu, likely because of its much smaller temperature range, indicating that surface curvature and temperature gradients dominate its stress magnitudes. Bennu's peak exfoliation stresses also happen at a smaller relative boulder size (~5× its skin depth) than on the Moon.

3.2 Exfoliation

Although Molaro et al. *[in review with Nature Communications*] describe how thermal fatigue leads to boulder exfoliation on Bennu by comparing spacecraft observations of boulder morphologies to simulations, it is relevant to review how the mechanism operates in some detail here because it directly informs the crack spacing and particle ejection calculations performed in Section 4.

Exfoliation is driven by thermally induced stresses that arise in boulder near-surfaces during daytime heating, as illustrated in Figure 1, which shows the stress field on a cross section through a boulder at mid-morning. As the boulder surface heats and moves into a state of compression, a region of tension develops in the near-surface associated with the spatial temperature gradient. As the Sun moves overhead, this tensile region expands westward and the location of its local maximum follows along a plane parallel to the boulder's surface. These stresses are oriented normal to the surface, pointing approximately in the Sun's direction and driving microcrack propagation along surface-parallel planes. Over time, microcracks can coalesce into larger-scale fractures, leading to the development of an exfoliation flake that separates from the boulder surface. Once it has begun to disaggregate, expansion and contraction of the flake itself

1   can aid in lengthening the underlying crack. The rate at which crack propagation occurs increases
2   as the crack length grows relative to the boulder size. When it nears a boundary (e.g., boulder
3   edge or material discontinuity), it may catastrophically disrupt and disaggregate all or part of the
4   flake. In terrestrial studies of sheeting joint exfoliation, crack lengthening is sometimes observed
5   to occur in small bursts during which pieces of the flake may break off and/or loose particles on
6   the surface become mobilized. This suggests that similar diurnal exfoliation "events" may be a
7   viable mechanism for particle ejection on Bennu. In Section 4, we will quantify the available
8   energy in these events that can go towards ejecting particles and estimate their sizes and speeds.

9   Terrestrial observations show that one or more surface-parallel fractures may develop
10 within the exfoliation region [*Martel*, 2017]. In three dimensions, the exfoliation stress field is
11 shaped somewhat like a spherical cap, and as a result the depth to which the stress orientation is
12 surface-normal (the exfoliation depth) is shallower than the depth of the local stress maximum at
13 the center (Figure 1). The exfoliation depth varies with time and is not symmetrical in all
14 directions, but typically falls between ~1 and 3 diurnal thermal skin depths, and may reach deeper
15 in some parts of the boulder due to interaction with other stress fields. This variation makes it
16 difficult to quantify the exfoliation stress consistently across boulder sizes and at different times
17 of day, so it is useful to use the stress magnitude at the local maximum as an upper limit. This
18 magnitude, which is controlled by both the boulder size and the diurnal thermal skin depth, is
19 reported as the maximum exfoliatian stress in Figure 2. The magnitude of stress at the exfoliation
20 depth is typically 50–80% of that at the local maximum and decreases towards the boulder surface
21 until entering the compressive regime (negative stress). Surface parallel fractures may develop at
22 any point shallower than the exfoliation depth where the stress and energy requirements to drive
23 crack propagation are met (Section 4).

24   It is unclear whether exfoliation features should exhibit a preferred orientation on boulder
25 surfaces. The development of microcracks along the exfoliation planes will occur over a broad
26 portion of a boulder surface as the exfoliation stress field sweeps from east to west. Because the
27 stress magnitude is highest in the afternoon, we might expect flakes to begin disaggregating from
28 the west side (for an equatorial example), forming a visible scarp that is oriented N-S on the
29 boulder's surface. On the other hand, there is N-S symmetry in the exfoliation field that produces
30 N-S stresses at the position of the local maximum, which could drive E-W fractures below the
31 exfoliation depth. As material is disaggregated from the surface, these E-W fractures could serve
32 to break up deeper exfoliation layers, producing visible E-W scarps on boulder surfaces. Both of
33 these trends would be influenced by latitude and the direction of solar heating, and to some extent
34 by boulder shape (Section 3.4 and Appendix B).

35 3.2 Other Expressions of Fatigue

36   The highest thermal stresses that occur in boulders undergoing thermal cycling are at their
37 surfaces during surface cooling at night. These are limited in depth to the upper thermal skin depth
38 and drive surface-normal crack propagation that is expected to contribute to shallow effects such
39 as surface disaggregation or granular disintegration. Many boulders on Bennu appear to be
40 breaking down in ways consistent with surface cracking, featuring loose particles seemingly
41 disaggregated from their surfaces, surrounded by unresolved material, or containing cracks that
42 follow apparent clast boundaries [*DellaGiustina and Emery et al.*, 2019; *Walsh et al.*, 2019;
43 *Molaro et al*, *in review with Nature Communications*]. Surface cracks are likely to be the dominant
44 mechanism serving to break up exfoliation flakes into smaller particles as they disaggregate. Even
45 if they do not cause disaggregation directly, any damage accumulated in the form of microcracks

1   at the boulder surface can weaken flakes, enabling pieces to break off during exfoliation events,
2   or making them more susceptible to breakup from impacts. Damage accumulation in the upper
3   few thermal skin depths may also increase the porosity of boulder surfaces relative to their less
4   damaged interiors. This will make it more challenging to constrain the thermal and mechanical
5   properties of Bennu's bulk materials from both spacecraft data and returned samples, which has
6   important implications for impact modeling and other research focused on understanding the
7   formation and evolution of rubble-pile asteroids. Different materials are more or less susceptible
8   to different types of damage accumulation depending on their mineral composition and fabric, and
9   therefore studying variation in surface thermal inertia with respect to the boulder population may
10   provide important insight.
11   Another expression of thermal fatigue that may be present on Bennu's surface is a
12   predominant N-S trend in the orientation of deep linear fractures in boulders, which has been
13   identified on both Earth [*McFadden et al.*, 2005; *Eppes et al.*, 2010] and Mars [*Eppes et al.*, 2015]
14   at locations near the ecliptic and equator, respectively. These fractures result from thermal fatigue
15   acting in the deep interior of boulders. Figure 3 (black solid lines) shows the stress orientation at
16   solar hour intervals throughout the day at the center of a 1 m boulder at Bennu's equator. These
17   remain approximately in the E-W (and cartesian z) plane, which tend to drive crack propagation
18   in the N-S direction at boulder interiors. These can coalesce into large-scale features that reach the
19   boulder edges and become visible at the surface. In some cases, they may become through-going
20   fractures that split boulders apart. As first identified in the field by McFadden et al. [2005], the
21   orientation of these stresses varies with latitude as the position of the boulder changes relative to
22   the Sun. At higher latitudes (Figure 3, green, blue, orange), the stress orientations shift towards a
23   NE-SW orientation. Dashed lines show its orientation at the time when the stress in the boulder
24   center is highest, with an aspect angle (degrees east of north) of 54, 35, and 25 degrees for boulders
25   at 20, 40, and 60 degrees latitude, respectively. The stress orientation never becomes truly N-S at
26   the highest latitudes, as it will always be influenced by the position of the Sun and the E-W
27   direction of its motion. However, this suggests that the trend in predominant fracture orientations
28   should shift from N-S near the equator towards NW-SE and NE-SW at higher and lower latitudes,
29   respectively.
30

Figure 3. Orientation of stress at the center of a 1 m boulder at the equator (black), 20 degrees latitude (green), 40 degrees latitude (blue), and 60 degrees latitude (orange) on Bennu at solar hour intervals. The black dashed lines show the orientation at the time of peak stress for each boulder above the equator.

1   Although they have been identified on Bennu's surface [*Walsh et al.*, 2019; *Molaro, in*
2   *review with Nature Communications*], it is difficult to determine whether any given linear fracture
3   is produced by fatigue or may be the result of impact damage. Impacts tend to create networks of
4   fractures oriented radially outward from the point of impact, but lower-energy events may also be
5   able to produce linear fractures, particularly in materials with a finer or more uniform grain size,
6   or those with planar fabrics or layering effects such as observed on Bennu [*Molaro et al., in review*
7   *with Nature Communications*]. Given that exfoliation has been observed, it is likely that some of
8   Bennu's linear fractures are also fatigue-driven. The latitudinal trend in orientations is observed
9   on both Earth and Mars [*McFadden et al.*, 2005; *Eppes et al.*, 2010; 2015] and should be visible
10 on Bennu if the magnitude of deep interior stresses is high enough to drive fatigue. These stresses
11 are lower than those near the surface which suggests linear fractures should develop more slowly
12 than those from exfoliation and surface cracking. Large through-going linear fractures are likely
13 to be most easily observed in larger boulders because they persist longer at planetary surfaces than
14 small boulders, and more energy is required to spatially separate disaggregated fragments from
15 each other. Rigorous statistical mapping of fracture orientations is needed to confirm whether this
16 effect is observed on the surface, which will in turn provide additional constraints on fatigue stress
17 thresholds and crack propagation rates for carbonaceous chondrite materials. Whenever possible,
18 thermal fatigue takes advantage of inherent weaknesses, layering effects, or pre-existing damage
19 to drive crack propagation, and these effects in real boulders will cause natural variation in the
20 overall fracture orientation trends predicted by the model. There is also evidence of mass
21 movement on Bennu's surface [*Walsh et al.*, 2019; *Barnouin et al.,* 2019], which may further
22 obscure such trends. Conversely, planar weaknesses from thermal fatigue could also be exploited
23 by impact processes which may reinforce the latitudinal trend.

24 3.4 Influence and Evolution of Boulder Shapes

25 Realistic shapes cause variations in the magnitude and timing of thermally induced stresses
26 experienced by different parts of a boulder. This may change where and how efficiently different
27 fatigue-driven features develop, but not the boulder's fundamental mechanical response to heating.
28 Although real boulders are not always well approximated by spheres, a different choice in our
29 approach would not qualitatively change our results. Though, their unique shapes can influence
30 the expression of thermal fatigue in some ways, due to face orientation and surface/shape
31 roughness. Boulders that are very angular and/or have highly sloped faces may experience
32 considerable changes in heating throughout the day, depending on their orientation with respect to
33 the Sun. For example, a highly sloped east-facing surface heats quickly at sunrise but also becomes
34 self-shadowed early in the day. As a result, it experiences a reduction in diurnal temperature
35 variation relative to another face and lower surface stresses may lead to less surface cracking. An
36 increase in local surface curvature due to surface roughness can have a similar effect. On very
37 angular boulders, faces that are oriented away from the Sun may receive little incident radiation.
38 Such an effect could serve to reinforce or retain the boulder's angular shape by only causing
39 degradation of the sunward-facing surfaces. Exfoliation may smooth or reinforce a boulder's shape
40 depending on the scale of surface or shape roughness relative to the thermal skin depth. Fractures
41 may develop underneath small-scale bumps and cracks on boulders, leaving a smoother surface
42 behind after a flake disaggregates. As the roughness of the shape approaches the scale of a few
43 thermal skin depths, different portions of the boulder may begin to behave like separate or disparate
44 segments, with exfoliation occurring independently on each. See Appendix B for additional
45 discussion on such effects.

1   Stress fields driving different fractures also interact differently in boulders of different size.
2   There is a synergy between interior and exfoliation stresses in boulders ≤ 1 m, for which the
3   diurnal thermal skin depth is a significant fraction of their size. In these cases, exfoliation stresses
4   on the E and W sides of the boulder are aligned and overlap with the deep interior stress field. This
5   may result in the more efficient development of through-going fractures at the expense of
6   exfoliation and/or deepening of exfoliation cracks, causing the distinction between the two features
7   to blur. Thermal fatigue is likely to have a strong interaction with the variety of rock fabrics and
8   textures observed on Bennu [*Molaro et al.*, *in review with Nature Communications*], and the
9   presence of layering effects in some rocks, particularly those ≤ 1 m in size, may cause the
10   deviation of exfoliation cracks from surface parallel to linear paths. As boulders become larger
11   growing to sizes ≥ 3 m, their western and eastern edges become more mechanically decoupled. It
12   takes longer for the nighttime surface stresses on their western edges to dissipate and the region to
13   become dominated by the daytime stress field as it overtakes the eastern hemisphere. Additionally,
14   western surface stresses have much greater magnitudes than in smaller boulders. This results in
15   large boulders retaining very strong stresses at their western surfaces and near-surfaces throughout
16   the day, which could perhaps lead to asymmetrical breakdown of boulders.

17   3.5 Annual Stresses

18   Due to its eccentric orbit, Bennu's solar distance varies between 0.89 and 1.36 au
19   throughout its 436.7 Earth-day year, resulting in an annual variation in surface heating. This annual
20   thermal cycle also induces tensile stresses that may drive thermal fatigue and/or influence the rate
21   and location of crack propagation caused by diurnal effects. The annual thermal skin depth is ~5.6
22   and 2.9 m for dense and porous boulders, respectively, allowing annual stresses to penetrate much
23   deeper than the diurnal effects that dominate their surfaces. As the diurnal thermal wave loses
24   contact with the interiors of large boulders, the exfoliation and interior stresses discussed above
25   wane and are replaced by analogous stress fields induced at greater depths at different times of
26   year. These stress fields start to become important in boulders with diameters >3 m, though their
27   effects are not included in our diurnal simulations above.
28   Annual stresses are challenging to model because spatially resolving both annual and
29   diurnal scales in the simulation requires extremely large mesh sizes and is very computationally
30   expensive. Using the same method described above, we simulated a 10 m equatorial boulder over
31   an entire Bennu orbit with the highest possible mesh resolution given the restrictions on
32   computation times. This resolution is still lower than acceptable for the diurnal simulations, and
33   therefore there is high uncertainty in the resulting magnitude of induced stresses. The stresses at
34   the boulder center and its near-surface, measured below the depth that diurnal surface stresses
35   reach, are on the order of 1 MPa and peak during perihelion approach. These are likely an
36   overestimate of actual annual stresses; however, given the order of magnitude agreement with
37   diurnal stress magnitudes, it is likely that that annual stresses are still great enough to overcome
38   the subcritical threshold needed to drive thermal fatigue.
39   In spite of the uncertainty in magnitude, the orientations of annual stresses can provide
40   insight into how they may influence rock breakdown. In the near surface, the stress orientation is
41   surface perpendicular during perihelion approach. This is caused by net heating of the boulder as
42   the asteroid moves closer to the sun, setting up a temperature gradient and stress field analogous
43   to diurnal exfoliation effects. On perihelion departure, net cooling is most efficient out of the N
44   and S faces of the boulder, which drives fractures in the E-W plane. At the boulder center, the
45   stress orientation alternates between E-W during perihelion approach and the z direction (surface-

1   normal) during departure, which is the same pattern as the diurnal stresses that drive N-S linear
2   fractures. This suggests that if annual stresses are strong enough to drive fatigue, such fractures
3   should be seen at both spatial scales and should develop most efficiently in boulders subject to
4   both diurnal and annual cycles, where their effects reinforce each other. A better understanding of
5   their relative rates is needed to assess how annual stresses may disaggregate large boulders and
6   the implications for the evolution of the boulder size-frequency distribution. In the near surface
7   especially, it is unclear to what depth diurnal effects may operate quickly enough to dominate
8   breakdown and whether annual fractures may be exposed by such disaggregation. Further, very
9   large boulders are likely to have substantial preexisting damage and structural inhomogeneities
10 that fatigue will exploit. These factors may make it difficult to identify annually driven features on
11 Bennu's surface, though boulder size may be one distinguishing constraint.

12   The magnitude of annual stress in boulders is greatest when oriented in such a way as to
13 drive an annual exfoliation effect in the near surface, suggesting that terrestrial sheeting joints may
14 be a relevant analog to observations. On Earth, the development of large-scale sheeting joints is
15 commonly attributed to erosion of overburden and other landscape-scale tectonic forces that result
16 in surface-perpendicular tensile stresses in the near surface, though as discussed by Martel [2017],
17 no current hypothesis is able to fully explain how these features develop. Joints occur as many
18 surface-parallel cracks with characteristic spacing that is thin near the surface and increases with
19 depth. They are similar to diurnal exfoliation layers but occurring at larger scales, with layers
20 ranging from millimeters to tens of meters thick [*Martel*, 2017]. Tectonic stresses are not expected
21 in a microgravity environment, but annual stresses could play an analogous role, driving the
22 development of surface-parallel fractures at depths below where diurnal effects operate. Recent
23 work [*Collins et al.*, 2018] has also shown that diurnal thermal cycling plays an important role in
24 how terrestrial sheeting joints exfoliate surface layers, suggesting that the superposition of annual
25 and diurnal sets of fractures and/or stress fields in the shallow near surface may influence the rate
26 and/or location of diurnally driven crack propagation. These factors highlight the complexity of
27 understanding how such features develop on asteroid surfaces and may help to explain the
28 observation of exfoliation layers on Bennu that are thicker than typical diurnal exfoliation depths
29 [*Molaro et al.*, *in review with Nature Communications*].

30 3.6 Influence of Volatiles

31 Although it is unlikely that volatiles from pore ice are present [*Rozitis et al.*, *in review this*
32 *collection*], Bennu's surface is dominated by hydrated phyllosilicate minerals, which may lead to
33 synergies with thermal fatigue. CM carbonaceous chondrites are largely composed of serpentine-
34 group phyllosilicates that contain tightly bound hydroxyl ions within octahedral sheets.
35 Dehydroxylation of serpentine can result from heating, comminution, and space weathering [*Drief*
36 *and Nieto*, 1999; *Nakamura*, 2005; *Lantz et al.*, 2015; *Thompson et al.*, 2019], resulting in both
37 pore space and molecular water. The former is caused by the volume change associated with the
38 dehydration reaction and may result in cracks that weaken the bulk material and enable water
39 migration (Tenthorey and Cox, 2003). The absorption of the water molecules onto crack walls can
40 lower their surface energy and therefore the critical stress threshold required to drive crack growth
41 [*Krokosky and Husak*, 1968; *Thirumalai and Demou*, 1970; *Kranz*, 1979], which may enhance and
42 accelerate the fatigue process. Indeed, laboratory studies have shown that hydrated carbonaceous
43 chondrite meteorites develop cracks under thermal cycling more quickly than anhydrous ordinary
44 chondrites [*Delbo et al.*, 2014]. If present, these effects may be analogous to those of
45 environmentally-assisted crack propagation (stress corrosion) which is thought to facilitate or

1   enhance fatigue in terrestrial environments [*Eppes and Keanini*, 2017]. However, the intrinsic
2   source of water in these materials has important implications for how boulders break down relative
3   to terrestrial observations. If thermal dehydroxylation occurs in Bennu's boulders, it cannot be
4   physically decoupled from the mechanical stresses that are induced by thermal forcing, and
5   therefore any effects from the process would be intrinsically captured in the material's effective
6   strength and Young's modulus. In this context, the properties of asteroid materials not only depend
7   on their composition, but also their temperature and age. This suggests that the efficacy of thermal
8   fracturing processes may vary widely between asteroids and asteroid populations, as well as
9   throughout their orbital and geomorphological histories. These effects are not directly included in
10 our simulations but would be reflected in the range of density and Young's modulus values of the
11 boulders, which currently are not known for Bennu.
12

13 **4 Crack Spacing and Particle Ejection**

14   We can use the results from our modeling to predict the spacing of surface-parallel
15 exfoliation cracks that may develop by quantifying the thermal strain energy density within the
16 boulder [*Fletcher et al.*, 2006]. The thermal strain energy is potential energy stored within an object
17 as it undergoes elastic deformation in response to a change in temperature. If there is sufficient
18 stress in an object to drive crack propagation, strain energy is released as the crack grows, which
19 provides the energy that goes into producing its new crack walls. For boulders undergoing diurnal
20 cycling, this energy is generated and stored in the boulder each cycle, providing energy for
21 progressive crack lengthening. The strain energy is highest in the late afternoon when they have
22 undergone the most expansion due to surface heating. This is the same time at which the exfoliation
23 stress is highest (and therefore exfoliation events are most likely) and represents the most amount
24 of energy available to propagate surface-parallel cracks during the day. As a result, exfoliation
25 events are of the most interest with respect to producing particle ejection, though we will also
26 consider events produced by surface cracking.
27
28

30 **Figure 4.** (left) Three-dimensional and (right) two-dimensional views of the layer geometry
31 assumed in our crack spacing and particle ejection calculations.

1   We assume that a fracture will form where the accumulated strain energy with depth is
2   equal to the surface energy of the new crack walls that will be created as a result. Our simulations
3   are three-dimensional so the strain energy density in the boulder is not spatially uniform in any
4   dimension. We take a linear profile of the strain energy density from the boulder's center to its
5   surface at the time and (surface) location where the peak value occurs. This we use as the depth-
6   dependent energy density of the boulder, making the simplifying assumption that it is uniform
7   along the surface-parallel plane. (These energy density profiles are included with the data available
8   in the repository noted in the acknowledgements.) We then calculate the depth (l) at which a
9   fracture will form, disaggregating the layer of material above it. We assume that this layer
10   fragments into many equally sized blocks with the dimension of the fracture depth (Figure 4). The
11   energy an individual block needs to contain for this to occur is:

12

13              $$E_n = 6\gamma l^2 \qquad\qquad\qquad (2)$$

14

15   where γ is the surface energy of the rock. Enough energy is needed to create six crack walls: four
16   vertical boundaries, one lower boundary, and the upper boundary of the layer below (Figure 4).
17   To determine the energy available (E_a) in the rock, we integrate the strain energy density (U) with
18   depth to obtain:

19

20              $$E_z = \int_{z=0}^{z'} U(z)dz \qquad\qquad\qquad (3)$$

21

22   and multiply it by the surface area in the other two dimensions, giving a total available energy:

23

24              $$E_a = E_z z^2 \qquad\qquad\qquad (4)$$

25

26   A fracture is assumed to form at the depth (l) at which the energy available in the block is equal
27   to the energy required ($E_a = E_n$), found using Eqs. (2) and (4). Once the depth of a given fracture
28   (l_n) is determined, the value of E_a is reset to zero and can begin accumulating once more such that
29   for $z > l_n$:

30

31              $$E_{z>l} = \int_{z=l_{n-1}}^{l_n} U(z)dz \qquad\qquad\qquad (5)$$

32

33   and:

34

35              $$E_a = E_z(z - l_n)^2 \qquad\qquad\qquad (6)$$

36

37   We could instead assume that a layer disaggregates as a cohesive, disc-shaped fragment,
38   but subsequent investigation into possible particle ejection speeds would require invoking an
39   additional energy source to then fragment the disc into smaller pieces. Although portions of flakes
40   may disaggregate cohesively, it is reasonable to assume that factors such as surface stresses at
41   different times of day and other mechanisms such as micrometeoroid impacts [*Bottke et al., in*
42   *review this collection*] will contribute to the breakup of flakes into smaller particles as they
43   develop. By choosing to incorporate the energy requirement for breaking up the flake into this
44   calculation, this method provides a more conservative estimate of the number of surface-parallel
45   fractures that can form as a result of exfoliating stresses and an upper bound on the largest expected

1 layer thickness. Any particles deposited atop boulders from other processes can still be mobilized
2 when an exfoliation flake experiences a lengthening event, but their numbers cannot be constrained
3 by this model.
4   The number of particles (N) into which each layer fragments can be calculated by taking
5 the volume of a spherical cap of height l_n, subtracting the layer above, and dividing it by the
6 volume of an individual cubic particle:

7

8 $$N = \frac{\pi}{3(l_n - l_{n-1})^3}[l_n^2(3R - l_n) - l_{n-1}^2(3R - l_{n-1})] \qquad (7)$$

9

10 where R is the boulder radius. This method provides a more conservative estimate than dividing
11 the flat area of the spherical cap by l_n^2, but it is ultimately an upper bound on the number of particles
12 into which flakes may fragment.
13   The previous calculation makes the assumption that a crack will form where there is
14 enough available strain energy. However, several factors may influence realistic crack depths and
15 can change the amount of available energy in a given exfoliation layer. Exfoliation layers form
16 progressively, and there must still be sufficient stress to drive crack growth at any given location.
17 Because stresses are weakest near the surface, the fatigue threshold to develop a crack may be
18 achieved at a greater depth than the required strain energy. At depths where the fatigue threshold
19 is met, thin layers may also develop more slowly due to lower stresses than layers at depth. Any
20 layer that disaggregates contains all available strain energy within its volume, including that which
21 Eqs. (2) to (6) assume goes into the development of shallower layers. Therefore, if those shallower
22 cracks are not propagating at the same rate as a deep crack, excess energy may be available beyond
23 what is needed to form the disaggregating layer. Other factors can also contribute to this. For
24 example, partially formed exfoliation flakes may become closer to the surface as material is
25 disaggregated, altering the depth where it is energetically favorable to propagate cracks and
26 requiring less energy to disaggregate new material. Structural weaknesses or pre-existing damage
27 in boulders could have similar effects. In any of these cases, excess energy may be available within
28 disaggregated particles that can go towards ejection.
29   If we prescribe that a single crack forms at some arbitrary depth, we can calculate the
30 amount of excess energy (E_e) available within particles using the same geometrical assumptions
31 as in Figure 4. In this case, none of the strain energy in the boulder goes into disaggregating layers
32 above that depth, so we use Eqs. (2) and (6) to find:

33

34 $$E_e = E_a - E_n \qquad (8)$$

35

36 This is converted to kinetic energy, ignoring the effects of microgravity, giving a particle speed:

37

38 $$v = \sqrt{\frac{2E_e}{\rho z^3}} \qquad (9)$$

39

40   Figure 5 (left) shows an example set of cracks for a dense 1 m boulder and the resulting
41 number of ejected particles (right). The model predicts layer spacing ranging from ~0.1 to 11 cm
42 and ~0.08 to 13 cm within the top 30 cm of dense and porous boulders, respectively, where
43 exfoliation is expected to occur. This range is consistent with the thickness of exfoliation layers
44 observed on Earth [*Holzhausen*, 1989; *Fletcher et al.*, 2006; *Martel*, 2017] and Bennu [*Molaro et*
45 *al.*, *in review with Nature Communications*]. It is also consistent with, though slightly wider in
1
2 **Figure 5.** (left) Available energy with depth into the surface of a 1 m boulder per Eq. 6. Dashed
3 lines represent the locations at which cracks form, dropping the available energy to zero. The crack
4 spacing ranges from 0.2 to 8.5 cm. (right) The number of equally sized particles into which flakes
5 disaggregate (Eq. 7), with each having the dimension of the layer thicknesses shown at left.
6
7
8 range than, the sizes of particles ejected from Bennu, which range from <1 to ~10 cm [*Lauretta*
9 *and Hergenrother et al.*, 2019]. The predicted minimum is somewhat lower than observed,
10 suggesting that if thermal fracturing is the driving mechanism for these events some particles may
11 not be resolved in spacecraft images. Layers are thinnest near the surface and generally increase
12 with depth, though not strictly monotonically. Larger boulders have more volume, which leads to
13 a higher total number of cracks. A majority of these are sub-centimeter in size due to the boulders'
14 higher strain energies, but the largest layers reach thicknesses of $\geq$10 cm. Typically, these boulders
15 had only one layer $\geq$10 cm thick within the upper 30 cm of their surfaces. Small boulders have
16 fewer total cracks, but more that are centimeters in size. This suggests that, as material is
17 disaggregated from the surface over time, large boulders may tend to show only the one or two
18 thick, underlying layers, whereas smaller boulders might show several layers, each a few
19 centimeters thick. Though, as layers disaggregate, multiple sets of cracks may become
20 superimposed on one another, highlighting the complexity of predicting crack spacing and particle
21 sizes in real boulders.
22   The predicted number of particles (Figure 5, right) produced by exfoliation of the layers
23 ranges from hundreds of centimeter-sized particles to thousands of sub-centimeter particles. The
24 number of particles grows as the diameter increases and boulders have larger cross sections of
25 material to disaggregate. Not all of these would be resolvable in spacecraft images, but still this is
26 higher than events observed at Bennu, which have produced of order ones to hundreds of particles
27 per event [*Lauretta and Hergenrother*, 2019; *Leonard et al.*, *in review with Earth and Space*
28 *Science*] (Table A1). Since very thin exfoliation layers will be removed first from boulder surfaces,
29 we will neglect the sub-centimeter particles for the time being and assume only the centimeter-
30 sized (and larger) layers remain. This is also a reasonable assumption considering stresses closest
31 to the surface are lowest in magnitude and therefore the smallest possible layers may not meet the
32 required fatigue threshold to develop.
33   The number of centimeter-sized particles ejected increases from tens in the smallest
34 boulders, to thousands in the largest boulders (Figure 5, right). This makes a reasonable

comparison to observations, especially considering that these are upper limit values, as exfoliation flakes are not expected to disaggregate all at once. Rather, they are expected to break apart over time, and therefore the number of particles in a full boulder cross section is likely an overestimate of what may be ejected in a single event. Additionally, the strain energy density in the boulder is not exactly homogeneous along the radially perpendicular axes, and may not possess enough energy to eject particles over its entire cross section, particularly at greater depths and in larger boulders. In some cases, the boulder face where exfoliation occurs may also be less than a full cross section, such as in our ideal boulder whose buried portion of the western hemisphere would be unaffected. In this context, it is more reasonable to expect some fraction of the flake to be ejected, which is also more consistent with observations. For example, an event that disaggregates one quarter of exfoliation flake from a 1 m boulder produces ~225 particles from the 1 cm layer, or ~75 particles from the 3 cm layer below. These are comparable to the largest events observed to date at Bennu. In a larger boulder, the flake fraction must be smaller to produce a similarly sized event. For example, one tenth of a 2 cm exfoliation flake disaggregated from a 5 m boulder produces ~200 particles. Without constraints on crack propagation rates, it is unclear what estimate for the flake fraction is realistic. In this sense, this prediction method gives a reasonable upper bound of tens to hundreds of centimeter-sized particles that can be produced via fatigue for ejection, but the lower bound is not well constrained.

While the calculations above estimate the number of equally sized particles disaggregated from a single layer, it is possible that multiple layers may be sourced during a given ejection event. If the exfoliation layer driving the event is not at the boulder surface, shallower cracks may facilitate breakup of the disaggregated flake into a population of particles with a range of sizes smaller than the flake depth. In this context, or considering the cumulative material disaggregated from boulders across multiple events, the full particle size-frequency distribution (Figure 5, right) gives us a sense of the overall population of particles, and relative number of particle sizes, that we expect to be produced by exfoliation-driven particle ejection events.

Taking the alternate approach, we can calculate particle ejection speeds from the surface of the 1 m boulder independently of the predicted spacing of exfoliation cracks. Figure 6 (a, solid) shows the thermal strain energy density over time at the boulder surface, with peak values in the afternoon an order magnitude higher than at other times of day. At this time (b, solid), the strain energy is highest at the surface and decreases strongly within 10 cm. Taking the depth as our layer thickness, the amount of available energy (c, solid) increases to hundreds of millijoules as particles grow in size. For dense boulders, this leads to particle ejection speeds (d, solid) ranging from ~0.3 to 0.8 m/s, which exceed Bennu's escape speed of ~0.2 m/s, and a minimum ejected particle size of 0.2 mm. We can also estimate particle speeds produced as a result of surface-perpendicular cracks (Figure 6, dashed lines) that develop during the night at boulder surfaces. These may provide a mechanism to break up exfoliation flakes, in which case their surface-perpendicular dimension would still be determined by the exfoliation layer thicknesses. The boulder has less thermal strain energy at this location and time of day, resulting in lower ejection speeds and a minimum ejected particle size of ~2.5 cm. If surface stresses produce cracks that do not interact with exfoliation layers, they may still contribute to the disaggregation of particles, but their spacing (and thus their speeds) cannot be predicted in the same way due to the differing geometry. Overall, this suggests that thermal fatigue can drive ejection events at night on Bennu's surface, but such events may be expected to be lower in energy and with slower-moving particles than those occurring in the afternoon.
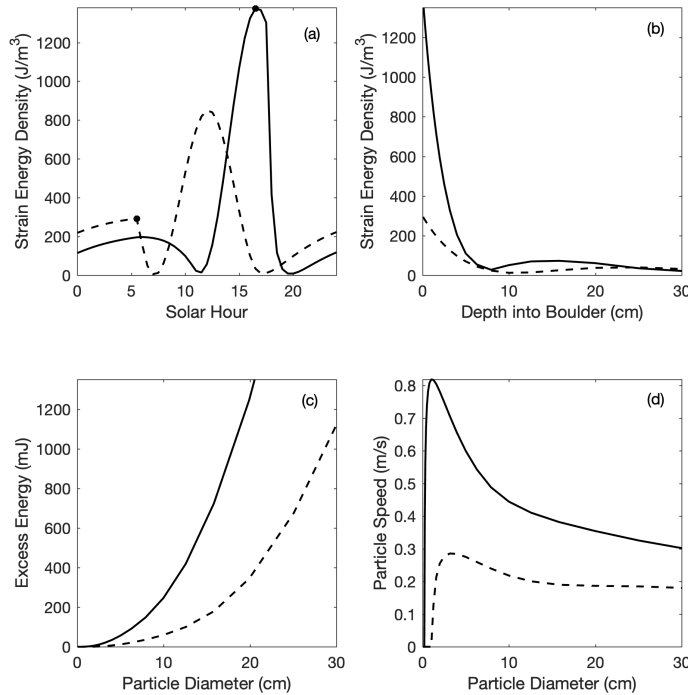

Figure 6. (a) Thermal strain energy density over one solar day at the location of peak thermal strain energy density (solid) and peak tensile stress (dashed) in a 1 m boulder, with the dots showing the time of day at which each occurs. (b) Profiles of the thermal strain energy density with depth from the two locations in (a) to the center of the boulder. (c) Excess energy available in particles with particle size. (d) Ejected particle speed with particle size. The x-axis on panels b and c is limited to the upper 30 cm where exfoliation and surface events are most likely to be initiated.

Figure 7 shows the maximum energy density (left) and ejection speeds (right) due to exfoliation (open) and surface cracking (solid) for dense boulders (circles) with varying diameter. The maximum ejection speeds are ~1.4 m/s for exfoliation events in large boulders. Ejection speeds due to surface cracking are much lower and do not occur in boulders <60 cm. Porous boulders have higher strain energy densities and ejection speeds than dense boulders because they have a lower elastic modulus and are less brittle. Since the magnitude of induced stresses are also lower, ejection events are less likely to occur or may occur less frequently in porous materials. The largest boulders porous are most likely to eject particles and have ejection speeds ~30 to 50% higher than the dense boulders, with a maximum of ~2 m/s. The smallest porous boulders have higher speeds by more than a factor of 4 but are the least likely to eject particles due to their low stresses. Overall, these speeds are consistent with particles ejected from Bennu, which ranged from ~0.05 to 3.3 m/s [*Lauretta and Hergenrother*, 2019; *Leonard et al.*, *in review with Earth and Space Science*]. The maximum predicted speed is lower (within a factor of 2) than what is observed, suggesting that although generally thermal fracturing is a viable mechanism for particle ejection, there is limited available energy relative to other processes such as impacts [*Bottke et al.*, *in review this collection*].

The amount of strain energy available in a given boulder varies throughout Bennu's orbit, peaking at perihelion when the diurnal temperature variation is largest. For a 1 m boulder, the change in peak strain energy with solar distance follows an approximate power law relationship with an exponent of –2.1. In contrast to Figure 6, the excess energy available to mobilize particles in a 1 m dense boulder at aphelion decreases to only a few hundred millijoules with a maximum ejection speed of 0.2 m/s. This is similar to the nighttime events, suggesting that the range of energies and ejection speeds for a given boulder size in Figure 7 are also a reasonable approximation for variation throughout the year. Since exfoliation layers are produced progressively, the number and depth of expected layers should realistically reflect some total

1 cumulative energy throughout the entire orbit. On the other hand, stresses are nonlinear with solar
2 distance and so we might expect crack spacings to skew towards what is expected at perihelion.
3   The particle sizes determined by Lauretta and Hergenrother et al. [2019] are for spheres,
4 whereas we assume cubes. It would be impractical to assume spherical particles using our
5 methodology because of its reliance on layer spacing to determine the sizes of particles and crack
6 walls. This will have only a minor effect on the comparison of our results to the observations. Most
7 notably, if we approximate that the integration of energy with depth would be the same as
8 performed above and simply split each cube into two smaller spheres, this would increase the
9 number of particles per layer by a factor of 2. However, given the order of magnitude nature of
10 our discussion regarding what fraction of a layer may disaggregate at once, a factor of 2 does not
11 change our conclusion qualitatively. Since halving the volume would also halve the total energy
12 of each particle, this would place a factor of 1/2 in both the numerator and the denominator of Eq.
13 9. These will cancel out, and therefore the particle speeds shown in Figures 6 and 7 would remain
14 unchanged. Lauretta and Hergenrother et al. [2019] assume a particle density of 2000 kg/m^3 in
15 their calculations, which falls between our solutions for dense and porous boulders.

16
17 **Figure 7.** Maximum thermal strain energy density (left) and ejection speed (right) for exfoliation
18 (open) and surface (solid) events in boulders of varying size. Values for dense (circle) and porous
19 (diamonds) boulders show the range of maximum energies and ejection speeds predicted for each
20 type of event.

23 **5 Observational Constraints on Ejection Events**

24   To determine the likelihood of thermal fatigue as a driving mechanism for Bennu's particle
25 ejection events, we must examine our results in the context of both observational constraints and
26 other possible mechanisms. A summary of our results with respect to observational constraints is
27 provided in Table 2, along with the references to which readers can refer for more details regarding
28 the ejection event observational data. A summary the data relevant to this discussion is also
29 included in Appendix C (Table A1). Given the limited dataset and difficulty in accounting for all
30 possible biases, there is uncertainty in some of the possible trends that we discuss. Nevertheless,
31 the data are compelling to explore and provide an opportunity to perform an initial assessment of
32 the feasibility of our hypothesis.
33

1   **Table 2.** A summary of our results with respect to constraints from observed particle ejection
2   events at Bennu. Constraints and supporting data are described in detail by Lauretta and
3   Hergenrother et al. [2019], Hergenrother et al. [*in review this collection*], Leonard et al. [*in review*
4   *with Earth and Space Science*], and Pelgrift et al. [*in review with Earth and Space Science*]
5   (Appendix C).

Constraints	Observations	Thermal Fatigue	Impacts*
Max Particle Speed (m/s)	~3.3	~2	>3.2
Particle Diameters (cm)	<1 to ~10	~0.08 to 13	~7 (upper limit)
Number of Particles	1s to 100s	10s to 100s (upper limit)	unconstrained
Total Mass (g)	1s to 1000s	10s to 1000s (upper limit)	350 (upper limit)
Time of Day	afternoon & night	afternoon (primary) & night (secondary)	any, afternoon preference
Frequency	days to weeks	unconstrained	biweekly near perihelion
Latitude & Longitude	various	any	any, preference equatorial

6   *Based on calculations of 7000-J impact events.
7
8
9   As described in Section 4, our model of crack spacing and particle ejection due to boulder
10 exfoliation and surface cracking is predicted to produce (i) a range of particle sizes from 1 mm to
11 13 cm, (ii) a maximum ejection speed of ~2 m/s, and (iii) up to hundreds of ~1 to 10 cm sized
12 particles per event. All three of these results are in good agreement with observations (Table 2),
13 though (iii) is the least well constrained. Our predicted maximum speed falls shy of the maximum
14 observed (3.3 m/s), however the majority of speeds from the three largest ejection events fall below
15 our best fit profile (Figure 8, left). Since our calculations are based on available energy per particle,
16 the lack of constraints on number of particles does not alter our predicted speeds.
17   The shape of the size-frequency distribution of our predicted particle population (Figure 8,
18 right) provides a good qualitative match to observations. Figure 8 (right) shows the predicted
19 particle size-frequency distribution compared to the combined distribution from the three largest
20 eject event observations. The two histograms reflect this combined distribution using the upper-
21 and lower-limit particle sizes from the observational data (Appendix C). The prediction for the 1
22 m boulder provides a good match to the observational distribution with lower limit particle sizes,
23 but predictions for larger boulders skew towards more smaller particles than are observed. If
24 Bennu's ejection events are caused by exfoliation, the relative lack of sub-centimeter sized
25 particles could indicate that we are not observing all of the material ejected during any given event,
26 or that the requirements to produce exfoliation layers at sub-centimeter depths is not achieved and
27 therefore such particles should not be produced. In reality, the total size-frequency distribution
28 predicted by our model should reflect the cumulative total predicted from all boulders which
29 produce particle ejections, however this is not yet known. Future work mapping boulder
30 exfoliation on Bennu's surface will provide better constraints.
31   Additionally, the timing of observed particle ejection events is consistent with the times of
32 day that exfoliation and surface cracking are expected to occur (Figure 9). Strain energy and
33 exfoliation stress for boulders ≥ 1 m are highest during local solar hours 13 to 18, with a peak
34 value at hour 17 (Figure 6; Figure 9). The majority of observed ejection events occur during these
35 times (dashed lines), with the four largest events (those with >20 particles) occurring
36 approximately between hours 15 and 18. The event that occurred during local night could have
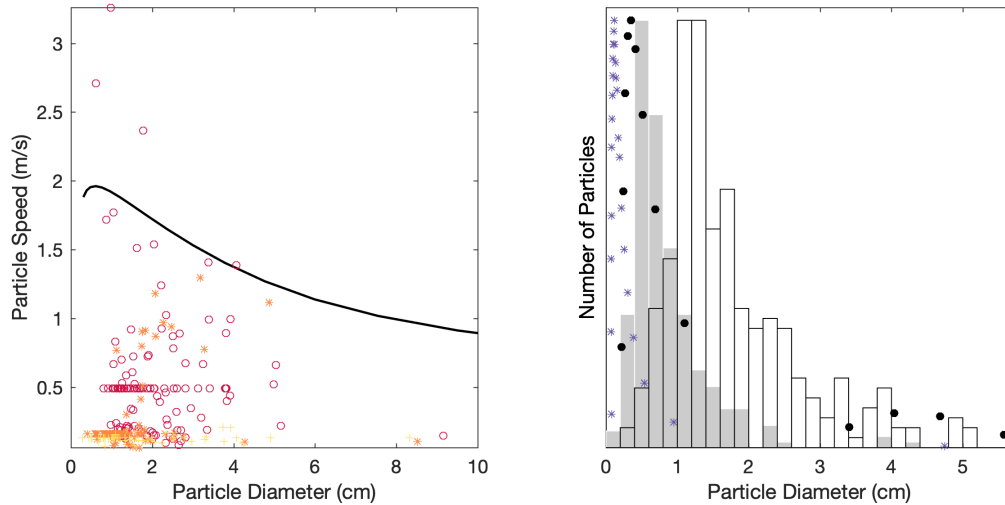

Figure 8. (left) Profile of the maximum ejection speed with particle diameter for a 6 m, porous boulder (black line), along with particle speeds and upper limit diameters from the three largest ejection events (symbols) as reported by Lauretta and Hergenrother et al. [*2019*] (Appendix C). The groups at ~0.5 and 0.16 m/s are particles with no trajectories for which the mean velocities were assumed. (right) Histogram of the upper limit (open) and lower limit (shaded) particle size-frequency distributions for the same ejection events, with predicted distributions produced from a 6 m, porous (asterisks) and 1 m dense (circles) boulder, where each distribution is normalized to its largest bin value.

been driven by surface cracking. The hours between sunrise and noon are the least likely for fatigue-driven ejection to occur. As discussed in Section 3.4, these time predictions will vary somewhat between individual boulders when accounting for their unique shapes.

The amount of strain energy available in a given boulder will peak at perihelion and decrease with increasing solar distance. Additionally, annual exfoliation stresses peak ~30 days before perihelion at a solar distance of 0.92 au. It is unlikely that deformation due to annual heating contributes any significant thermal strain energy to boulder surfaces, however the superposition of annual and diurnal stresses during this time may help overcome fatigue stress thresholds or increase crack propagation rates, leading to more frequent events. Combined, these factors suggest that if Bennu's particle ejection events are driven by thermal fatigue, we should observe more frequent, higher energy events approaching and near perihelion, and less frequent, lower energy events near aphelion. Higher energy events are also expected to produce more, faster moving particles. This is generally supported by the data, which shows that the total energy of events does decrease with increasing solar distance. Though, the three largest events are spread out over several months with lower energy events in between. Events with speeds exceeding 1 m/s have also been observed at solar distances $\gtrsim$1.3 au [Pelgrift et al., *in review with Earth and Space Science*]. This is not consistent with our predicted decrease in particle speeds near aphelion. More observations are needed to better explore this idea.

While the observations of particle ejection events at Bennu are consistent with what we predict from thermal fatigue, other candidate mechanisms have not been ruled out. In particular, electrostatic lofting and impacts have been considered as alternatives for Bennu, though other mechanisms are also explored generally by Jewitt et al. [2015]. Hartzell et al. [*in review this collection*] report that, depending on the surface cohesion, electrostatic lofting is capable of
Figure 9. Time of day at which peak surface (solid) and exfoliating or near-surface (open) stress occurs in boulders of varying diameter. The dashed lines show the times of nine ejection events observed at Bennu (see Appendix C).

17
18 stripping Bennu of submillimeter sized particles during the day, but cannot produce the large, fast
19 particles observed leaving Bennu's surface during the largest ejection events. Ultimately, they
20 conclude that it is unlikely to cause Bennu's daytime ejection events but cannot be ruled out as a
21 mechanism for smaller events that occur during the night. This leaves impacts as the most
22 reasonable alternative candidate to thermal fatigue (Table 2).
23   Bottke et al. [*in review this collection*] report that 7000-J meteoroid impacts at Bennu are
24 predicted occur on a biweekly cadence near perihelion with a preference to strike in the late
25 afternoon. They compared these impacts to the three largest ejection events and found the timing
26 to be a reasonable match to observations. They find that these impacts, on average, can produce
27 up to 350 g of ejecta, with 80% of the mass having a speed <3.2 m/s if they assume that the impacts
28 strike into cohesionless (1 kPa) soil. This ejecta mass is consistent with low to midrange values of
29 the total masses of observed ejection events, though it can only produce the largest observed
30 individual particles if ejected as a single combined mass (maximum of ~7 cm diameter). In this
31 context, the impact hypothesis may be somewhat mass-limited compared to the largest ejection
32 events, but the available energy is more than enough to produce observed ejection speeds. This is
33 in contrast to thermal fatigue, which can potentially produce an excess number of particles relative
34 to observations, but with maximum speeds less than the fastest observed particles. This being said,
35 Bottke et al. [*in review this collection*] only perform calculations for 7000-J impact events (Table
36 2) which does not capture the probabilistic variation in impactor energy and size that occurs in
37 reality. The limited number of ejection event observations are insufficient to perform any statistical
38 analysis which may provide a better comparison to their results. Both hypotheses predict that
39 impact frequency should decrease towards aphelion.
40   One weakness in the impact hypothesis is the nature of the impactor target. The cohesive
41 strength of rock is equal to its shear strength under zero confining pressure and typically is the
42 same order of magnitude as its tensile strength. The impact model uses dry sand as an analog for
43 cohesionless material, which has a cohesive strength two orders of magnitude lower than even
44 weak and porous intact rock [e.g., *Burk*, 1964; *Grott et al.*, 2019]. Bottke et al. [*in review this
45 collection*] report that impacts occurring into cohesionless material can produce the observed mass
46 or particle speeds from the three largest ejection events, but impacts into intact rock cannot.
47 However, the majority of Bennu's surface is covered with intact boulders which have enough

1 strength to sustain visible fractures and therefore cannot be considered cohesionless. Further, they
2 report that an impact into cohesionless soil should produce a crater at least 14 cm wide, which
3 would excavate at least 260 cm^3 of material and require a soil depth of 3 to 4 cm to occur (assuming
4 its shape is a spherical shell). Both of these factors suggest that only a fraction of Bennu's surface
5 has properties suitable to produce impact events consistent with ejection event observations, which
6 would lead to a less frequent cadence of ejection events than they report and therefore provide a
7 worse match to observations. On the other hand, the nature of impacts into rubble pile surfaces is
8 not well understood, and it is unclear at what size materials transition from unconsolidated small
9 rocks to adjacent intact boulders, or how these regimes are influenced by impactor energy.
10 While fatigue provides a good match to observational constraints at the present time, more
11 observations are needed to explore long term variation in the mass, energy, and frequency of
12 particle ejection events. Additional work studying exfoliation features on Bennu's surface will also
13 provide better constraints fatigue thresholds and lead to more accurate predictions of mass
14 disaggregation rates from our model. It is also likely that fatigue works in synergy with both
15 impacts and electrostatic lofting to produce the asteroid surface we see, and all three mechanisms
16 may contribute to observed ejection events. For example, if stress magnitudes are sufficient for
17 exfoliation can produce sub-centimeter sized layers, electrostatic lofting could help sweep away
18 the smallest disaggregated particles to leave behind the underlying centimeter scale layers we see
19 in boulder surfaces. Such an interaction could help to explain the lack of sub-centimeter sized
20 particles in observed ejection events relative to the particle population predicted by our model.
21 Because exfoliation flakes develop progressively, fatigue may also provide planes of weakness
22 that meteoroid impacts can exploit. Even if the ejection events are ultimately driven by impact
23 processes, it is likely that the exfoliation layers play a strong role in the particle size distribution
24 of impact ejecta both leaving and remaining on Bennu's surface.
25

6 Conclusions

27 We performed finite element simulations of stress fields in carbonaceous chondrite
28 boulders undergoing diurnal thermal cycling on the surface of Bennu and find their magnitudes
29 comparable to the tensile strength of terrestrial analog materials. These stresses are sufficient to
30 drive thermal fatigue (subcritical crack growth) as an active process on the surface and might drive
31 other thermal fracture processes (e.g., thermal shock) as well. The occurrence of thermal fatigue
32 on the asteroid surface has been confirmed by the observation of fatigue-driven exfoliation on
33 Bennu's boulders [*Molaro et al., in review with Nature Communications*], which likely works in
34 combination with surface cracking to drive breakdown. The development of linear fractures is also
35 likely to occur, though more work is needed to better constrain the stress threshold for driving
36 fatigue. Thermal fatigue likely plays a dominant role in Bennu's landscape evolution, and future
37 work to identify and study fatigue-driven features will provide valuable insights into the rate at
38 which the process occurs and how it interacts with other surface processes. Analysis of returned
39 samples will also provide better constraints on the thermal and mechanical properties of Bennu's
40 surface materials, which have a critical bearing on induced stress.
41 We quantified the thermal strain energy stored by boulders during the times of day at which
42 exfoliation is expected to occur to predict the characteristic spacing of exfoliation layers. We find
43 that layers should be thinnest near the boulder surface where the strain energy is highest and
44 increase with depth, with predicted crack spacings of order 1 mm to 10 cm. This is consistent with
45 observations of exfoliation layers on Bennu's boulders [*Molaro et al., in review with Nature*

1 *Communications*], as well as in terrestrial environments [*Holzhausen*, 1989; *Fletcher et al.*, 2006;
2 *Martel*, 2017]. We also find that exfoliation flakes can disaggregate into an upper limit of hundreds
3 of centimeter-sized particles, although this result is less well constrained. The ejection speed of
4 such particles mobilized during an exfoliation event is predicted to increase with decreasing
5 particle diameter and to have a maximum value of ~2 m/s for porous boulders. Dense boulders
6 have a lower maximum speed of ~1.3 m/s, and in both cases ejection speeds generated during
7 surface cracking events at night are much lower. These predictions are in good agreement with the
8 sizes and speeds of particles from ejection events observed at Bennu to date by the OSIRIS-REx
9 spacecraft [*Lauretta and Hergenrother*, 2019; *Leonard et al.*, *in review with Earth and Space*
10 *Science*]. The shape of the size-frequency distribution of the particle population exfoliation is
11 predicted to produce is also consistent, though it skews toward a greater number of sub-centimeter
12 particles than is observed. If fatigue is driving the observed ejection events, this would indicate
13 that we are not observing all of the particles ejected, or that the fatigue threshold is not met near
14 the boulder surface and therefore sub-centimeter exfoliation layers are not produced. More
15 observations are needed to confirm some of the trends in event frequency and energy that are
16 predicted to occur.
17   We posit that thermal fatigue provides a good match to observations and is a likely
18 explanation for the particle ejection phenomenon observed at Bennu. If it does play a role, this has
19 broad implications for our understanding of active asteroids and the asteroid population as a whole.
20 Previous works have hypothesized that thermal fracture processes may generate activity on active
21 asteroids with small perihelion distances, such as 3200 Phaethon [*Jewitt and Li*, 2010]. Our results
22 support this hypothesis. With a diurnal temperature variation of hundreds of degrees, Phaethon's
23 surface is likely to be subject to thermal shock processes, with fatigue operating at depth to weaken
24 and prepare the rock for disruption. However, the fact that thermal fatigue alone may be capable
25 of generating activity suggests that there may be many more active asteroids than are currently
26 known, likely including many in near-Earth space. With less energetic activity, a lack of tails or
27 comae would make such bodies harder to identify from ground-based observations. Objects with
28 a similar rotation period and composition to Bennu should begin generating strain energies capable
29 of ejecting particles at solar distances of ~1.5 to 2 au. This activity "line" for different bodies will
30 vary primarily with composition, as an object's mechanical properties control how it responds to
31 thermal forcing. Fatigue may also become possible on some bodies at greater distances than
32 activity can occur, for example because the strain energy is insufficient to mobilize particles in a
33 given gravity environment. There is much to be learned about how this process operates. For
34 example, it is unclear what roles crack propagation distance and rate play in producing ejection
35 events, or to what extent breakup of exfoliation flakes occurs during such an event or beforehand.
36 A better understanding of these ideas will provide valuable insights into the distribution of active
37 asteroids in the solar system and their mass loss rates, which has implications for asteroid survival
38 times and the production of interplanetary debris.
39
40
41

Appendix A: Model Uncertainties

At the time at which the peak surface stress occurs, its value should theoretically be the peak stress anywhere in the entire boulder's volume. The uncertainty values for surface stress in Figure 2 are determined by taking the maximum stress anywhere in the boulder at the time when peak surface stress occurs and subtracting the value of the peak surface stress from the two-dimensional cross section. This accounts for uncertainty in the exact location of the peak value along the axis perpendicular to the cross section. An additional 10% of the peak stress value is added to account for any enhancements or reductions in stress due to mesh resolution. This causes higher stresses to have higher uncertainty values, which is appropriate because these factors will always produce a stronger effect in simulations with more stress. This same method is also used to calculate uncertainties for exfoliation stresses in boulders <1.5 m. Stresses in the deep interior are never the highest in the boulder's volume, and therefore the uncertainty is set at 10% of its value.

For boulders ≥1.5 m, another source of uncertainty in exfoliation stress comes into play. An additional thermal stress field on the east side of boulders arises from a different physical effect that overlaps with the exfoliation stress field and enhances stress magnitudes in the overlapping region. This moves the location of the peak stress at that time of day, causing it to no longer reflect exfoliation stress alone. The location of exfoliation stress alone is needed to maintain consistency with our measurements for smaller boulders. In these cases, the location of the exfoliation local maximum was determined by eye, and the uncertainty was determined by taking the difference in stress magnitude at that location from the peak magnitude of the second stress field. Because the latter is higher, this uncertainty accounts for any possible reduction in the exfoliation stress due to location, or enhancement due to the additional stress field or due to mesh resolution. An amount 10% of the exfoliation local maximum stress was also added to these uncertainties.

Appendix B: Influence of Boulder Shape

Although real boulders are not necessarily well approximated by spheres, our choice to use spherical boulders does not qualitatively change our results. Boulder shape can influence the nature of thermal fatigue in two primary contexts: face orientation and surface/shape roughness. In both cases, realistic shapes will cause variations in the magnitude and timing of thermally induced stresses experienced by different parts of the boulder. To explore these effects, we simulated a 1 m square boulder embedded at an angle in the regolith and a 1 m spherical boulder with 10 cm deep triangular surface "cracks" spaced 10 cm apart (Figure A1). The variation in stress magnitudes in each case (described below) is smaller than ±25%, which is comparable to their uncertainty values and to stress sensitivity to variation in mechanical properties [*Molaro et al.*, 2017]. No color scale is included in Figure 1A because these simulations were performed at a lower resolution for computational efficiency, and so this stress variation represents an upper limit on behavior.

Surface stresses are primarily influenced by surface orientation. For boulders that are especially angular, the orientation of an individual face with respect to the Sun's location and direction of motion will influence the timing and amount of incident solar radiation it receives. For example, the square boulder (Figure A1, top) has a highly sloped east face, which will heat very quickly at sunrise, but it will also become self-shadowed earlier in the day than a lower-sloped

surface. This will cause it to experience a lower diurnal temperature variation and a reduction in the magnitude of surface stress. This effect may be enhanced by the fact that it has more surface area from which to emit radiation compared to a sphere. An increase in local surface curvature at a given location due to surface roughness or bumps can also lead to decreased surface stress.

Exfoliation stresses are influenced primarily by boulder shape, depending on the scale of surface or shape roughness. Exfoliation fractures will develop underneath small-scale surface bumps and may leave behind a smoother surface after the flake disaggregates. As the roughness of the shape approaches the scale of a few thermal skin depths, different portions of the boulder may begin to behave like separate segments, with exfoliation occurring independently on each. For example, the square boulder (Figure A1, b) has two local maximums in exfoliation stress at each corner which peak at two different times of day. The stress orientation near each corner is still surface-normal in this case, and the surface-parallel crack propagation could serve to round them over time. The stress orientation between corners is more difficult to describe with respect to the boulder's angular shape. Below the exfoliation depth the stress orientation is determined by which boulder faces provide the most efficient pathway for cooling. In spherical boulders, this is N-S, but in this case the stress between the two corners is roughly E-W. This aligns with the surface-normal stress at the western corner which may lead the boulder to develop a flat western face. The stress magnitude is also enhanced at the western corner (relative to a spherical boulder) due to the corner orientation with respect to the time at which the boulder is hottest. In this sense, exfoliation is also influenced by surface orientation to the extent that it determines which boulder faces experience exfoliation and how they heat. In contrast, the exfoliation stress field in Figure A1 (d) remains largely unchanged from a spherical boulder, and the stress orientation in the "bumps" remains normal to the spherical shape of the surface as if the cracks did not exist. In this case exfoliation would serve to cut through or under the bumps. There is nuance in how the stress fields change and behave in irregular objects, and much to still be learned about the evolution of boulder shapes from thermal fracturing.

Figure A1. (a) Temperature of a square 1 m boulder in the midafternoon being heated by the Sun as it moves within the y plane, and (b) a cross section through the boulder along the y plane. Panels (c) and (d) show the same for a spherical boulder with 10 cm surface "cracks."

Appendix C: Summary of observational data

Table A1 summarizes some of the relevant data from nine particle ejection events observed between January 6 and April 19 of 2019. These data are compiled from Lauretta and Hergenrother et al. [2019], Hergenrother et al. [*in review this collection*], Leonard et al. [*in review with Earth and Space Science*], and Pelgrift et al. [*in review with Earth and Space Science*] for use in Figure 8, Table 2, and the text in Section 5. Table 1A reports the number of *observed* particles during each ejection event, which may differ from the number of *analyzed* particles in the aforementioned studies. The photometry techniques used to estimate particle sizes were performed using a range of assumed particle albedos. Following the methodology described by Lauretta and Hergenrother et al. [2019], we use a density of 2000 kg/m^3 and albedos of 0.15 and 0.033 to provide lower- and upper-limit estimates, respectively, on observed particle diameters for Figure 8. Tables 2 and A1 show values assuming an albedo of 0.044, which yields a midrange estimate of particle sizes. These data (Table 1A) may be a useful reference with regards to the comparison between ejection mechanisms in Section 5. However, we also caution that the total number of observed events is limited, making it difficult to assess how statistically meaningful any specific trends may be. There may also be biases in the timing of observed events, and the number and albedo of observed particles, resulting from spacecraft location, orientation, distance from the asteroid, and other factors.

Table A1. Summary of data from the particle ejection events observed at Bennu compiled from Lauretta and Hergenrother et al. [2019], Leonard et al. [*in review with Earth and Space Science*], and Pelgrift et al. [*in review with Earth and Space Science*].

Event Date	Solar Distance (au)	Solar Hour	No. Observed Particles	Maximum Speed (m/s)	Total Energy (mJ)	Total Mass (g)	Particle Diameter (cm)			References
							Ave	Min	Max	
6 Jan	0.89	15.36	200	3.3	270	1800	1.2	<1	8	Lauretta and Hergenrother et al. [2019]
19 Jan	0.9	16.63	93	1.3	100	600	1	<1	7	Lauretta and Hergenrother et al. [2019]
