Abstract

Precision yield data is commonly recorded by modern combine harvesters and can be used to help growers optimize their operations. However, there have been very few attempts to predict variation in yield within a given field using multispectral satellite data. We used a precision yield dataset gathered in canola (*Brassica napus* L.) crops in central Alberta, Canada, and a time series of medium-resolution Sentinel-2 data collected over the growing season. Using two mapping methods, random forest regression and functional data analysis, we were able to predict crop yield to within 12-16% accuracy of actual yield, and to capture within-field variation. Our results demonstrate that time series of medium-resolution multispectral imagery is capable of mapping small-scale variation in crop yields, presenting new research and management applications for these techniques.

Keywords: crop yield; time series images; functional linear regression; random forest regression

1. Introduction

Precision agriculture (PA) uses technological innovations to increase production by conducting the right management practice at the right time and place. PA has been practiced commercially since the 1990's (*Mulla, 2013*) and is now deployed widely across the North American agricultural sector. For example, in the United States, guidance systems are used in about half of all planted acres, and GPS-based yield mapping and variable-rate technology are used in about 40% and 30% of operations, respectively (*Schimmelpfennig, 2016*). Adoption is even higher in Canada, as a survey by Agriculture and Agri-Food Canada indicated that 84% of Canadian farmers are currently using PA and have combine yield monitoring capability, and 75% of participants said they would use more PA in the future (*Steele, 2017*).

Remotely sensed imagery is a key data source for PA, summarizing soil properties (e.g., organic matter, moisture, pH) or plant conditions (e.g., crop nutrients, biomass, yield, water/heat stress, weed infestation, insects and plant diseases) (*Thorp & Tian, 2004; Liaghat & Balasundram, 2010; Ge et al., 2011; Mulla, 2013; Chlingaryan et al., 2018*). Crop yield maps are perhaps the most important data products for crop management, and medium-resolution multispectral satellite datasets ($\geq$ 10-meter) have long aided in this objective, providing insights at coarse resolution over large areas (*Bauer et al., 1978; Rudorff & Batista, 1991; Doraiswamy et al., 2004; Bala & Islam, 2009; Liu et al., 2010; Salmon et al., 2015; Hunt et al., 2019; Sakamoto et al., 2020*). However, airborne multispectral, airborne hyperspectral, and high-resolution satellite imagery have typically been favoured for PA because of a closer match to the scale of variation typically observed within fields.

Medium-resolution multispectral satellite data has several advantages that make it attractive for use in PA. First, it is often free to the public, while the high-resolution or hyperspectral data can

42 be costly. Second, medium-resolution multispectral platforms (such as Landsat 8 or Sentinel-2)

43 offer extra spectral bands, including Red Edge and Shortwave Infrared, which are useful in crop

44 mapping and monitoring (*Liu et al., 2004; Herrmann et al., 2010; Delegido et al., 2013; Braga*

45 *et al., 2020*). Lastly, data products from the medium-resolution multispectral satellites, especially

46 those from space agencies such as NASA (National Aeronautics and Space Administration),

47 JAXA (Japan Aerospace Exploration Agency), and ESA (European Space Agency), are already

48 preprocessed to high-quality for time series analysis.

49 To our knowledge, only *Thenkabail (2003)* and more recently *Hunt et al. (2019)*, have attempted

50 to use medium-resolution satellite imagery for monitoring within-field conditions. *Thenkabail*

51 *(2003)* showed that Landsat Thematic Mapper images can be used to quantify between- and

52 within-field variation in biophysical quantities (e.g., Leaf Area Index, biomass) of six crops, and

53 classified quantities with an overall accuracy of 81%. They found a significant relationship

54 between combine yield monitor data and Landsat-derived NDVI ($R^2 = 0.77$). *Hunt et al. (2019)*

55 produced high resolution wheat yield maps at 10-meter resolution using Sentinel-2 imagery in

56 random forest regression models (RMSE of 0.61 tonnes/ha). Incorporating environmental

57 datasets further improved predictions (RMSE of 0.66 tonnes/ha). Although *Thenkabail (2003)*

58 and *Hunt et al. (2019)* have successfully demonstrated that medium-resolution satellite imagery

59 can be used in mapping precision crop yield, there remains potential to improve mapping

60 method, and to better capture within-field variation. In addition, as climate, crop type and its

61 spectral response can vary greatly due to geographic location, more studies are still needed to

62 demonstrate the performance and limitations of medium-resolution imagery in precision

63 agriculture across a broad range of field conditions.

64 Our objective in this study is two-fold. First, we aim to demonstrate the capability of medium-

65 resolution multispectral satellite imagery, e.g. Sentinel-2, in mapping precision canola yield (dry

66 seed mass in tonnes/ha). Second, we propose two yield mapping approaches that can be applied

67 to any climate region and crop type. Because a single observation in time may not represent the

68 best yield-spectra relationship, we propose two mapping methods that utilize the rich Sentinel-2

69 time series images. Accuracy of the proposed approaches is assessed by mean-absolute-errors

70 (MAE) and a visual comparison between actual and predicted yield maps. Our results show how

71 medium-resolution satellite imagery can be used to predict within-field yield variability, and they

72 have potential applications in variable-rate fertilization and the evaluation of within-field and

73 whole-field profitability. In addition, because our proposed mapping approach depends only on

74 the presence of a remote sensing time series, and on no other geographically-determined

75 variables, there is potential to extend it to other areas and crop types.

76 # 2. Data and methods

77 ## *2.1. Data*

78 ### 2.1.1. Precision canola yield

79 We used precision yield data from eight canola fields (CF) located in the County of Vermilion

80 River, Alberta, Canada (relative locations are shown in order to protect the data owner's privacy;

81 Figure 1). Fields were seeded using three canola varieties (Liberty L234, L255, and Pioneer

82 P501) in May of 2019, using standard seeding densities (~60 plants/m^2). Fields were treated with

83 pre-emergence herbicide, and 1-2 passes of post-emergence herbicide, depending on weed and

84 stand establishment. From late August to October, fields were first swathed and then harvested

85 using a Case IH 8230 combine with a 10.7 m header bar. Precision yield data was recorded in

86 segments by the combine's on-board yield monitor. Each segment is characterized by a starting

87   position of the combine (Figure 2b), width of the header bar (m), direction of travel (0-360° N),

88   the length of a recorded segment (m), and the total dry mass of canola (tonnes). We used these

89   attributes to construct harvested segments (polygons) within each field (Figure 2c), and

90   rasterized the yield from all polygons using an area-weighted average yield (tonnes/ha) for each

91   pixel of the Sentinel-2 images (Figure 2c,d). We only retained pixels that had at least 95% of

92   their area covered by harvested polygons (Figure 2).

93

94   Figure 1. Relative locations of canola fields (CF1-CF8) with precision yield data shown using a UTM-

95   based pseudo coordinate system (both axes are in meters). The fields for the three training scenarios

96   (see Section 2.3.3) are separated by coloured lines.
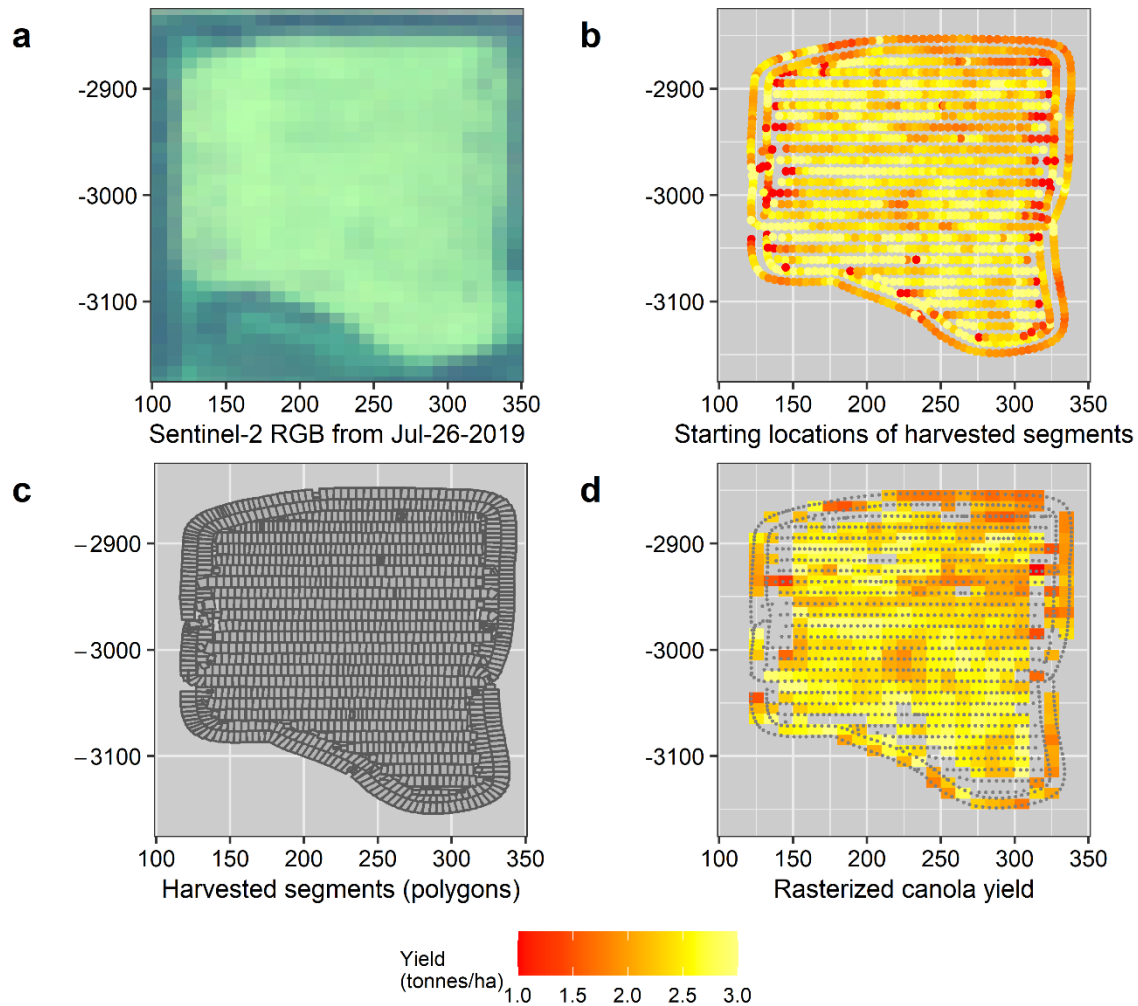

Figure 2. Preparation of precision canola yield from raw yield monitor data at CF4: (a) a sample

Sentinel-2 RGB image of the field, (b) starting positions of the harvested segments, (c) harvested

segments that were constructed from recorded attributes, and (d) precision canola yield in raster.

Axes are in a UTM-based pseudo-coordinate system (meter)

2.1.2. Sentinel-2 images

Sentinel-2 is a European wide-swath, high-resolution, multi-spectral imaging mission. The

mission specification of the twin satellites is designed to give a high revisit frequency of 5 days

at the Equator. Each satellite carries an optical instrument payload that samples 13 spectral

bands: four bands at 10 m (including Red, Green, Blue and NIR), six bands at 20 m, and three

107   bands at 60 m spatial resolution. There are two Sentinel-2 products available for users: Level-1C

108   (top-of atmosphere reflectance) and Level-2A (bottom-of-atmosphere reflectance). Both

109   products are available in 100x100 km^2 tiles and delivered free-of-charge through multiple

110   sources, including the Google Earth Engine (GEE) platform. In this study, we used Level-1C

111   product—the only product available for the study area through the GEE.

112   We downloaded all top-of-atmosphere Sentinel-2 tiles between Apr-01-2019 and Oct-31-2019

113   from GEE. A built-in cloud/snow mask was applied for each image to remove unreliable

114   observations. In total, 67 Sentinel-2 images were available for the study area (Table 1). Among

115   eleven spectral bands, only seven were used in the study, including three visible (B2-Red, B3-

116   Green, B4-Blue), two NIR (near infrared, B8 and B8A), and two SWIR (shortwave infrared, B11

117   and B12) bands. After cloud/snow filtering, the remaining good observations in each band were

118   stacked to create a time series dataset at each pixel.

119   Table 1. Sentinel-2 images used in the study.

Field Name	# of images	DOYs (days-of-year)	# of good obs.	# of pixels
CF1		96, 98, 106, 108, 111, 113, 118, 121, 123, 126, 131, 133, 136, 138, 141, 143, 146, 148, 151, 153, 158, 161, 163, 166, 168, 171, 173, 176, 178, 183, 186, 188, 191, 193, 196, 201, 203, 206, 208, 211, 213, 216, 218, 221, 226, 228, 231, 236, 238, 243, 246, 248, 258, 261, 263, 266, 273, 276, 278, 281, 283, 286, 288, 291, 293, 301	40	3358
CF2			43	4604
CF3			37	6933
CF4	67		42	440
CF5			40	4839
CF6			40	1868
CF7			41	3269
CF8			36	10826

120

121   Using the seven spectral bands, we also computed two spectral indices: normalized difference

122   vegetation index (NDVI; *Tucker, 1979*; *Huete et al., 1997*) and normalized difference water

123   index (NDWI; *Gao, 1996*). NDVI [(NIR - Red)/(NIR + Red)] is an indicator of the greenness of

124   the biomass (photosynthetic activity) while NDWI [(NIR - SWIR1)/(NIR + SWIR1)] is known

125   to be strongly related to the plant water stress, making these two indices good proxies for plant

126   health and productivity.

127   A current trend in remote sensing is to utilize a time series dataset to explore the spectral

128   signatures of studied objects, as a single snapshot image may not capture the best relationship

129   between an object of interest and its corresponding spectral signature. In addition, observations

130   were often not uniform within and across fields due to a limited swath width and cloud cover,

131   making a single-image approach impractical. There are two common approaches for using time

132   series: (1) generating statistical composites of spectral bands and indices (statistical features)

133   over a given time window, (e.g., growing season) and (2) reconstructing the time series to

134   retrieve gap-free dataset at every pixel. In this study, we assessed both approaches of exploiting

135   time series images in mapping precision yield.

136   #### Statistical features

137   From the time series of seven spectral bands and two indices, we computed six sets of annual

138   statistical features, including the Min, Max, Mean, and 10th, 50th, and 90th percentiles of each

139   pixel. For each Sentinel-2 tile, 54 composites (9 data layers x 6 statistical features) were

140   generated.

141   #### Reconstructed NDVI and NDWI time series

142   Since the masking process on GEE is not able to completely remove unreliable observations

143   from Sentinel-2 images (Figure 3), we applied an additional filter (Appendix A) to further reduce

144   noise in the NDVI time series. Masked data points in the NDVI time series were also removed

145   from the NDWI time series. We then retrieved daily NDVI and NDWI values between Apr-01

146   and Oct-30 (day-of-year or doy: from 91 to 304) from the corrected time series by a simple linear

147   interpolation (Figure 3).

148

149   Figure 3. Reconstruction of NDVI time series at a sample location (pixel) of CF7. The additional filter

150   was applied to further reduce noise in the GEE-retrieved (original) NDVI time series. Daily NDVI values

151   (reconstructed NDVI) were obtained from the corrected time series by a simple linear interpolation.

152   Note that additional filter cannot completely remove cloud-contaminated observations (e.g., at DOY

153   280) but majority of large noises were successfully removed.

154   ## *2.2. Mapping precision canola yield*

155   We used two statistical approaches for modelling canola yield given a time series of remotely

156   sensed images. First, we used statistical features of each pixel as inputs into a random forest

157   regression (RFR; *Breiman, 2001*). RFR has been used widely in agricultural remote sensing to

158   predict crop health and development using spectral information (*Zhou et al., 2016*; *Liang et al.,*

159   *2018; Hunt et al., 2019; Sakamoto, 2020*). Secondly, we used functional data analysis (FDA;

160   *Ramsay & Silverman, 2005*) to predict the canola yield using the reconstructed NDVI/NDWI

161   time series, because it is more natural to think about plant growth as a continuous process (in a

162   functional form of NDVI/NDWI time series) rather than sequence of individual observations. A

163   specific type of FDA—functional linear regression (NDVI/NDWI time series) with scalar

164   responses (canola yield)—was used in this study (*Kokoszka & Reimherr, 2017*).

165   ### 2.2.1. Random Forest Regression

166   Random forest regression is an ensemble of randomized regression trees, each created with a

167   random subset of training samples and features. The random forest predictor is then retrieved by

168   averaging the results of all individual trees. Performance of RFR—prediction accuracy and

169   computational time—can vary widely due to size of the sample dataset (*sample_size*) as well as

170   the tuning of hyper-parameters (e.g., the number of regression trees: *n_estimators*, the number of

171   features tested at each node: *max_features*, and the minimum number of samples required to split

172   an internal node: *min_sample_split*). We experimented with different parameter settings,

173   deciding on the following "optimal" settings (good balance between prediction accuracy and

174   computation time) : *n_estimators* = 200, *max_features* = 54, *min_sample_split* = 20, *sample_size*

175   = 50% of available pixels. We performed all random forest regression in Python using *scikit-*

176   *learn* library (*Pedregosa et al., 2011*).

177   ### 2.2.2. Functional Linear Regression

178   A functional linear regression (FLR) models crop yield, *y*, as:

179    $$y = f(X,\beta) + \varepsilon = \int X(t)\beta(t)dt + \varepsilon \qquad \text{(Model 1)}$$

180   where *X* is the value of a predictor variable at time *t* (NDVI and/or NDWI, in our case), while β

181   is the instantaneous effect (slope) of that variable on *y*. One way of estimating *β* is to present the

182   parameters (*β*) and the functional covariates (X_i) as a finite sum of pre-defined basis elements:

183 $\beta(t) = \sum_k \beta_k \theta_k(t) = \theta' b$; $X_i(t) = \sum_k c_{i,k} \psi_k(t) = C\Psi$. Replacing β and X of model 1 by their new

184 forms results in model 2—a typical multiple linear regression.

185 $$y = f(X, \beta) + \varepsilon = C\Psi\theta' b + \varepsilon = Zb + \varepsilon \qquad \text{(Model 2)}$$

186 We performed the functional linear regression between precision canola yield and remote

187 sensing time series in R using the *fda.usc* package (*Febrero-Bande & Oviedo de la Fuente,*

188 *2012*). We tested different types of basis functions for both β and X, and FLR using a B-spline

189 basis (order of 4 and 4 control points) returned the best yield prediction.

190 ### 2.2.3. Training-testing scenarios and accuracy assessment

191 We divided the eight canola fields into training fields and testing fields (Figure 1), in order to test

192 how well an empirical model from a given area performs in another area with no reference data.

193 Three training-testing scenarios were examined (Figure 1, Table 3). In all scenarios, we

194 intentionally left CF5 in the testing set, because this field displayed obvious patches of

195 higher/lower canola yield that would be helpful in evaluating performance of our models.

196 <div align="center">Table 2. Training-testing scenarios</div>

Scenario	Training Fields	Training Pixels	Testing Fields	Testing Pixels
S1	CF2, CF3, CF7	14806	CF1, CF4, CF5, CF6, CF8	21331
S2	CF1, CF2, CF6, CF7	13099	CF3, CF4, CF5, CF8	23038
S3	CF3, CF7, CF8	21028	CF1, CF2, CF4, CF5, CF6	15109

Note: RFR models used only a half of "Training Pixels"

197

198 Performance of both RFR and FLR in mapping precision canola yield was compared using

199 Mean-absolute-errors (MAE) at scenario-level and through a visual inspection of yield maps and

200 regression residual maps.

201 # 3. Results

3.1. Descriptive statistics of precision canola yield

Figure 4 shows the descriptive statistics for precision canola yield (tonnes/ha) measured at the field-level and scenario-level. There was substantial variation between fields (Figure 4a). The least productive field (CF3; median value of 2.138 tonnes/ha) had approximately 18% lower yield than the most productive field (CF5; median value of 2.592 tonnes/ha). Across the three scenarios, S3 showed the most similar yield distribution between the training and testing fields (Figure 4b), while in other two scenarios, the testing fields were clearly more productive than the training fields. This is especially so in S1 where the difference in median yield was 13.7%.

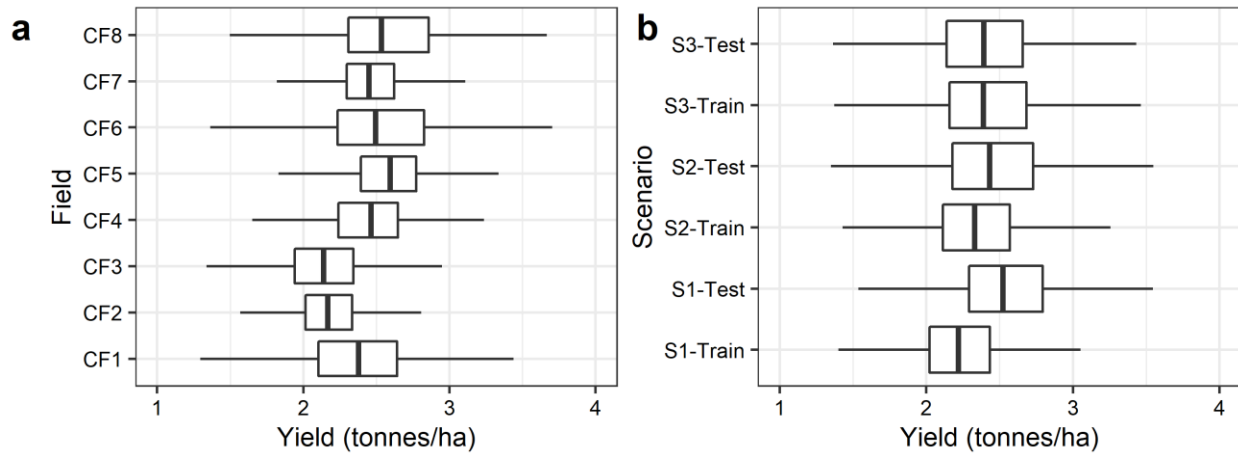

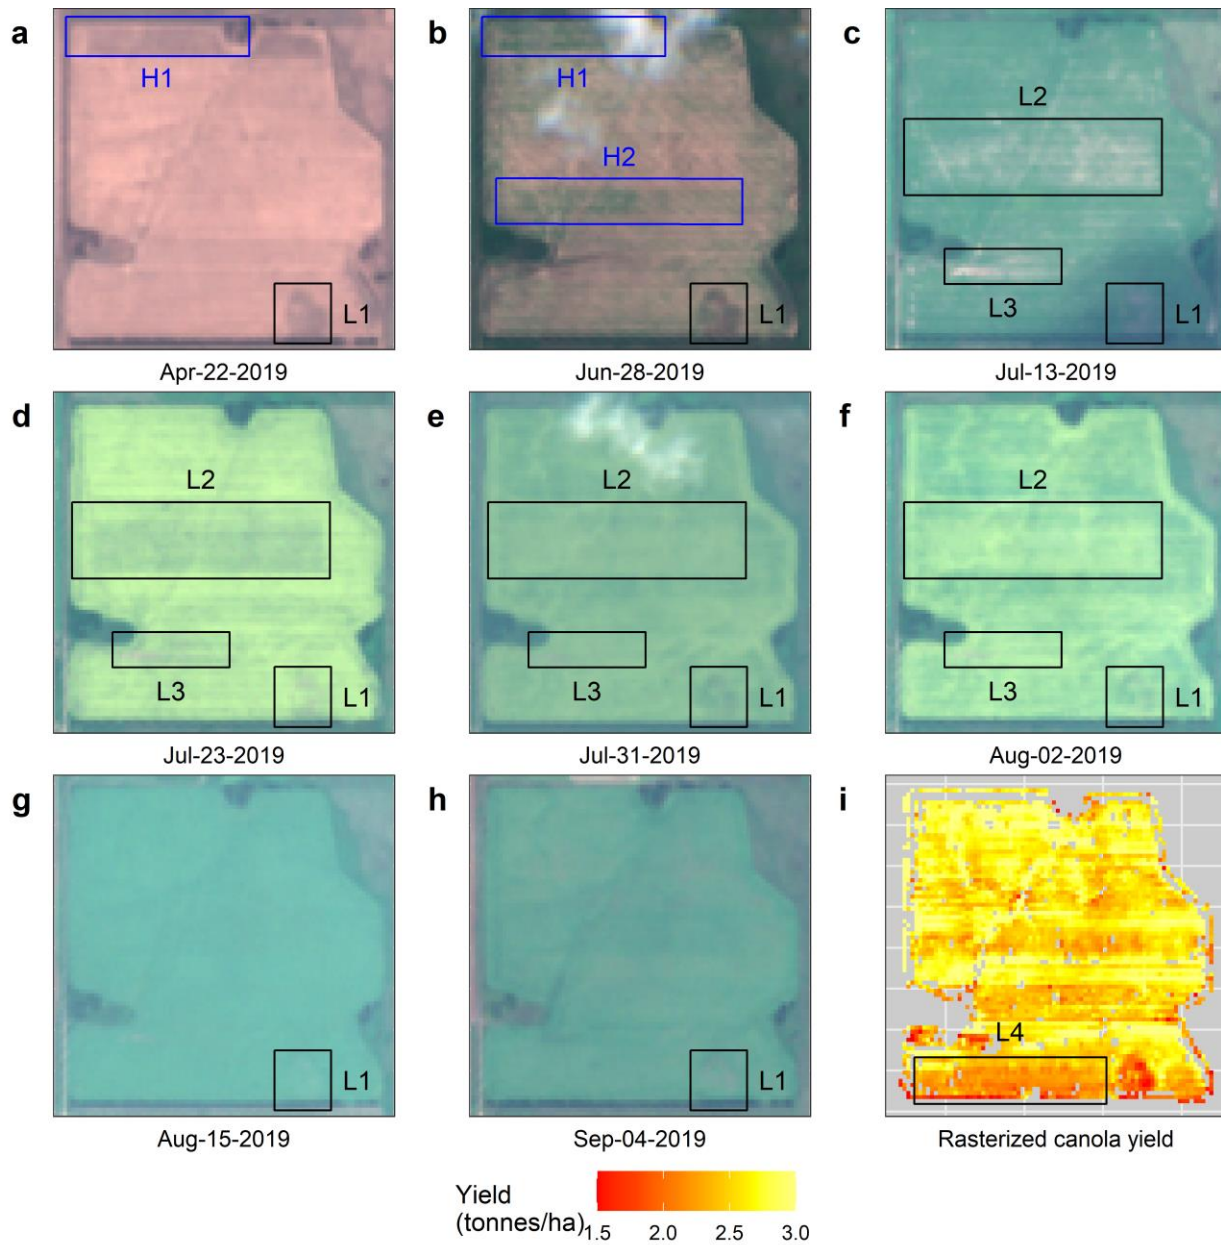

Figure 4. Distribution of precision canola yield at the (a) field level and (b) scenario level.

3.2. Qualitative visual analysis

Visual inspection of CF5 over the growing season (planted: May-15-2019 and harvested: Sep-24-2019; Figure 5a-h) revealed patches where canola productivity was lower (black boxes: L1, L2, L3) or higher (blue boxes: H1, H2) than other areas of the field. Soil conditions in the field are partly visible in the pre-planting image, where two patches appear darker than other parts (blue and black boxes; Figure 5a). Day 43 after the planting (Jun-28-2019), while most of CF5 was still soil-coloured, two patches—one at the top (H1) and another in the middle of field

219 (H2)—showed a strong green signal (Figure 5b), while the small patch at the bottom-right corner

220 (L1) is still shaded in dark soil colour. Two weeks after that (Jul-13-2019), while the canola has

221 greened up on most of CF5, a few patches still appear greyish (Figure 5c). Although L1 did not

222 appear clearly in Figure 5c because of cloud cover, it is still easy to see that canola did not grow

223 well there. Low or high growth patches of CF5 remained on RGB images until after flowering

224 (flowering: Jul-23-2019, early ripening Aug-02-2019), especially at L1. RGB images at the end

225 of season did not show differences between low or high growth patches (Figure 5g,h). The

226 spatial distribution of canola yield (Figure 5i) is clearly reflected in the RGB images (Figure 5a-

227 b), but we also observed a patch of lower yield at the bottom edge of the field (L4) that was not

228 reflected in the visual inspection.

229 NDVI and NDWI images over the growing season were also related to canola yield (Figure 6).

230 Similarities between yield and NDVI/NWDI were clearly visible in early season images (Jun-28-

231 2019). While the pattern of low / high growth continued until very late in the canola season (Sep-

232 04-2019) in the NDVI images, we did not see strong correlation between yield and NDWI after

233 Jul-13-2019, except at L1 and L3. L1 and L3 showed consistently lower values in NDVI and

234 NDWI over the entire season.

Figure 5. Sentinel-2 RGB images over the growing season (a to h) and precision canola yield (i) of CF5. L1, L2, and L3 indicate low-yield patches, while H1 and H2 indicate high-yielding patches, demonstrating that spatial patterns in yield are sometimes visually discernible across a time series of true colour imagery.
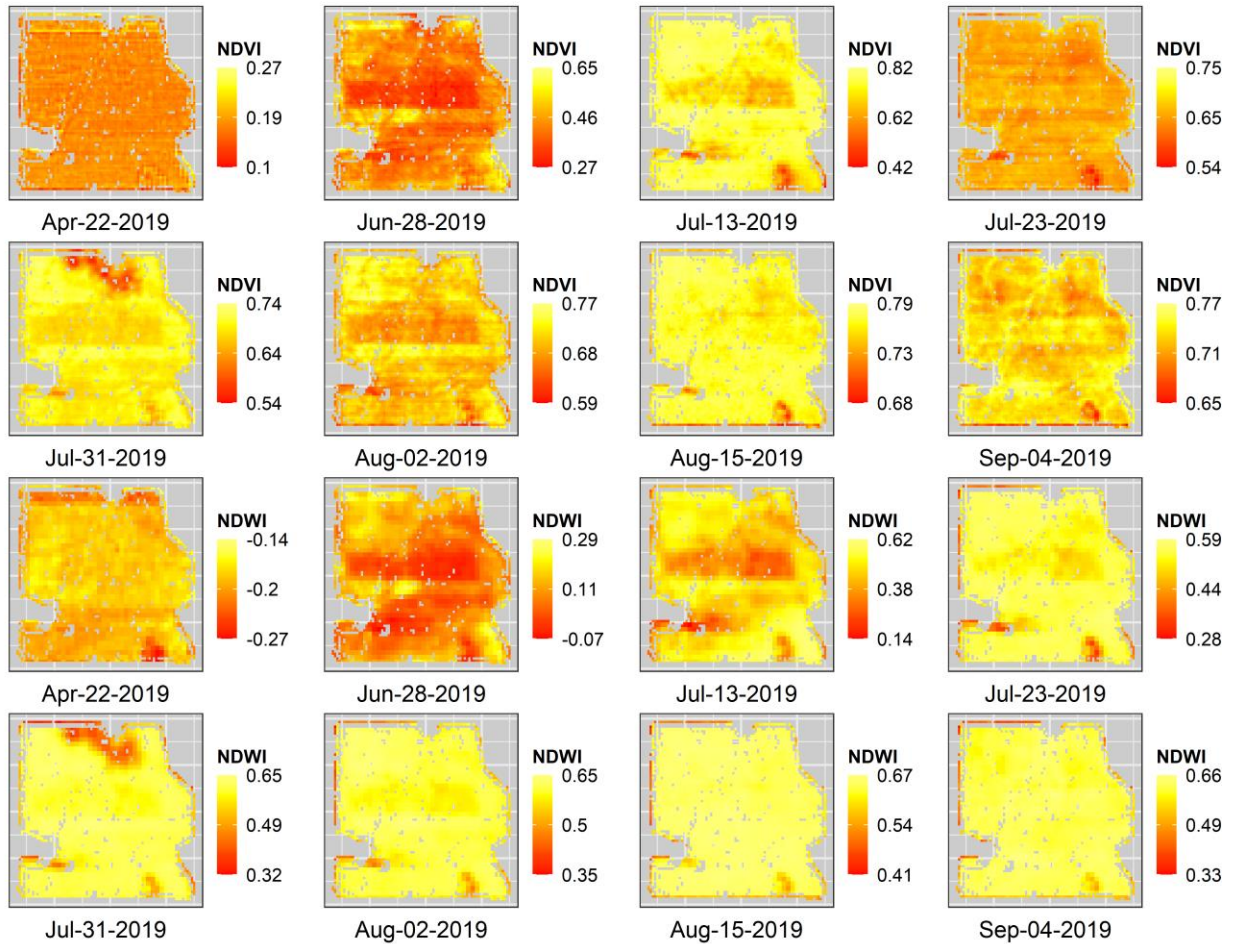

Figure 6. Snapshots of NDVI and NDWI over the growing season at CF5.

3.3. Predicted canola yield: Random Forest Regression vs. Functional Linear Regression

RFR had better prediction accuracy in the training datasets but performed similarly to FLR on testing datasets (i.e., out-of-field prediction; Table 3). S3 had the lowest prediction error, but differences between S3 and the other two scenarios were minor. Although RFR clearly performed better for the training fields, predictions of FLR were slightly more accurate for all three scenarios, indicating that RFR was likely overfitting. Overall, the testing MAEs on the testing dataset ranged from 300 to 390 kg/ha, approximately 12.6% to 15.5% of the median yield in each scenario. FLR models using solely NDVI or NDWI time series were similar, but the

250 NDVI time series provided more spatial detail due to the finer resolution of NDVI images (Red

251 and NIR: 10 m, SWIR1: 20 m). Using both NDVI and NDWI yielded the best predictions in

252 scenarios S1 and S3.

253 Table 3. Mean-absolute-errors of RFR and FLR. Both approaches performed similarly on the testing

254 dataset with MAEs equivalent to 12%-16% of the median yields.

Scenario	Model	MAE Training (tonnes/ha)	MAE Testing (tonnes/ha)	MAE Testing (% of Median)
S1	FLR_NDVI	0.2152	0.3465	13.74
S1	FLR_NDWI	0.2281	0.3232	12.82
S1	FLR_Both	0.2082	0.3382	13.42
S1	RFR_Stats	0.1035	0.3912	15.52
S2	FLR_NDVI	0.2605	0.3207	13.20
S2	FLR_NDWI	0.2775	0.3212	13.22
S2	FLR_Both	0.2568	0.3486	14.35
S2	RFR_Stats	0.1299	0.3412	14.04
S3	FLR_NDVI	0.2732	0.3045	12.74
S3	FLR_NDWI	0.2650	0.3136	13.12
S3	FLR_Both	0.2624	0.3005	12.57
S3	RFR_Stats	0.1191	0.3014	12.61

FLR_NDVI: FLR using only NDVI time series; FLR_NDWI: FLR using only NDWI time series;
FLR_Both: FLR using both NDVI and NDWI time series; RFR_Stats: RFR using statistical
features

255

256 The results from field CF5 are helpful for explaining our overall results. Figure 7 shows

257 predicted canola yield maps of CF5 from both RFR and FLR for three scenarios using a heat

258 map (low yield: Red → high yield: Yellow). All yield maps were able to predict areas with the

259 lowest yield (L1 and L3). Spatial yield patterns in FLR maps, especially in S3, appear to match

260 the yield data better than those from RFR as they successfully predicted higher yields in H1 and

261 H2, and lower yields in L1 to L3. However, none of models were able to predict a patch of lower

262 yield at the bottom of CF5 (L4).

263   Figure 8 shows the spatial distribution of residuals (predicted - actual) in field CF5, showing

264   distinct areas of negative and positive residuals. Both FLR and RFR predictions overestimated

265   the actual canola yield in the northern part of the field. Predictions in scenario S3 are less biased

266   as we see a good balance between the blue-green and the yellow-red colours (Figures 8f, 8i). In

267   all three scenarios, both RFR and FLR consistently overestimated yield in areas with low actual

268   values (especially in L4) and underestimated yield in areas with high actual values. Histograms

269   of residuals (Figure 8d-f, 8j-i) confirm that the predicted yield maps underestimated the actual

270   canola yield for field CF5. Median yield residuals in scenarios S1 and S2 (-0.2256, -0.3392 and -

271   0.3406, -0.2140 tonnes/ha for FLR and RFR, respectively) were more positively biased than

272   those in S3 (-0.0942 and -0.0101 tonnes/ha for FLR and RFR, respectively).

Figure 7. Spatial pattern of actual vs. predicted canola yield at CF5. L1-L4 (black boxes) indicate low-yield patches, while H1 and H2 (blue boxes) indicate high-yield patches. Both NDVI and NDWI time series were used in FLR models.
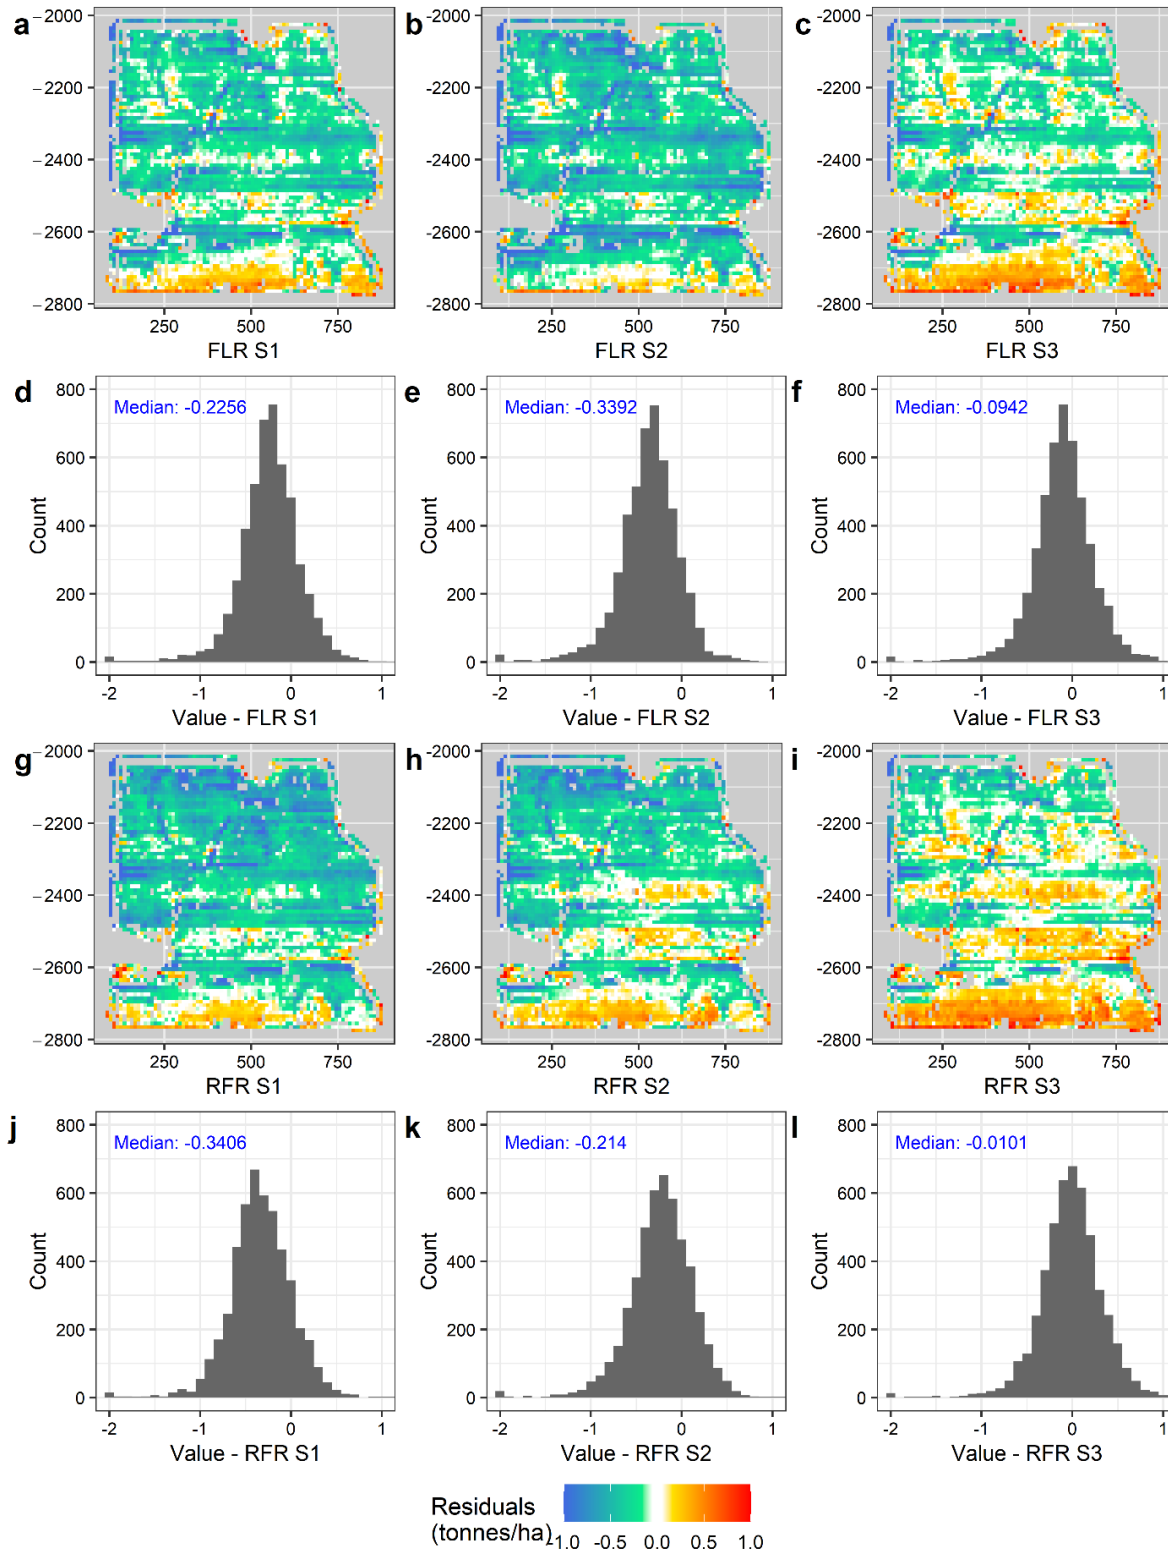

277

278   Figure 8. Spatial distribution and histogram of residuals at CF5 (predicted - actual). Both NDVI and

279   NDWI time series were used in FLR models.

280 ## 3.4. Contribution of remote sensing features in canola yield mapping.

281 We evaluated the contribution of remote sensing variables in both FLR (Table 4) and RFR

282 (Table 5) for S3—the most accurate scenario. Those results help to explain findings in the

283 previous section that patches of low or high growth were identifiable from early season NDVI

284 images and were still distinguishable late in the season (around the end of the canola ripening

285 stage). The early season NDWI image (Jul-13-2019) also showed a similar pattern with canola

286 yield.

287 Among the 5 components of the NDVI b-spline basis, #3 and #4 were the more significant and

288 larger (in terms of absolute values) than the other three (Table 4), suggesting that satellite

289 observations around the peaks of those components were most influential for prediction—day

290 200 (flowering stage) for #3 and day 255 (early in the ripening stage) for #4 (Figure 9). Five

291 components of NDWI were equally significant. In S3, the FLR model using NDVI performed

292 better than the model using NDWI, meaning that FLR models picked up more information from

293 the NDVI signal.

294 We aggregated scores of strongly correlated statistical features: "min" and "10th percentile" into

295 "low", "mean" and "50th percentile" into "medium", "max" and "90th percentile" into "high".

296 The RFR models showed that the peak NDVI value and the median NDWI value were the most

297 important variables for predicting yield (Table 5). Peak NDVI is often observed in the later-

298 season pod-ripening stage. The second most important feature was "medium" value of NDWI,

299 which was observed around the end of the stem-elongation stage at approximately Jul-16-2019.

300 Table 4. Summary of FLR model using both NDVI and NDWI time series for S3 scenario.

4. Discussion

It is worth noting that the eight canola fields cover a large area of approximately 360 hectares (36,137 pixels). However, canola growth dynamics and its corresponding spectral response still might not be fully captured in a few large and homogeneous training fields.

At the field-scale, our predicted yields had MAEs ranging from 0.30 to 0.39 tonnes/ha, equivalent to 12.6%-15.5% of the median yields (Table 3). This result is promising for several reasons. First, we predicted precision yield at a medium spatial resolution (10 m). Secondly, even though our reference dataset was relatively small (only 8 canola fields), our method was still able to predict well. Lastly, no ancillary data, such as soil moisture, climatic conditions, crop variety, or agricultural practices, were integrated into any of our models. Those variables are commonly used inputs of crop yield mapping (e.g., *Prasad et al., 2006*; *Jeong et al., 2016*; *Kern et al., 2018*). Nevertheless, our MAEs are in the same range as those reported in *Mkhabela et al., 2011* (0.08 – 0.4 tonnes/ha), which forecast regional canola yield in the Canadian Prairies based on a simple regression that used multiple-years of MODIS-derived NDVI to predict yield statistics.

Our prediction accuracy could probably be improved slightly if the training and testing pixels were selected randomly from the data pool (the training data would contain pixels from all studied fields). However, our purpose in selecting training or testing datasets was not only to achieve the highest prediction accuracy but also to create a geographic gradient to test how well an empirical model from one area performed in another area without reference data.

Our results showed that both RFR and FLR models performed the best in scenario S3 (Table 3). One possible reason for this was that the similarity in yield distribution between the training and testing datasets were highest for S3 (Figure 4b). A further examination of CF5 indicated that the models consistently underestimated canola yield of this field (Figure 8). This outcome is

329 reasonable because CF5 is the most productive field (Figure 4a) and the training dataset is likely

330 not able to capture the complete yield dynamics of the field. In terms of spatial accuracy, we

331 observed that both RFR and FLR maps successfully captured patches of low or high canola

332 yields. However, residuals were not spatially homogeneous. Our predicted maps overestimated

333 values in low-yield areas (L1-L4) and underestimated values in high-yield areas (H1, H2). This

334 is likely caused by the noisy reference dataset. For example, operating the yield monitor without

335 crop flowing through the combine will reduce the recorded yield. Additionally, yield monitors

336 must be cleaned periodically, as debris can accumulate on the sensor surface, causing sensor drift

337 over time (Producer-cooperator, *pers. comm.*). Our accuracy assessment focussed on CF5

338 because this field presented a distinctive pattern of high and low yield patches. Our intention was

339 to demonstrate that using moderate resolution satellite images, we can capture accurately within-

340 field variations of canola precision yield.

341 Another aim of this study was to examine two different approaches to using time series data in

342 yield mapping: statistical features (input to a Random Forest Regression) and functional data

343 (input to a Functional Linear Regression). While RFR is a robust machine learning algorithm

344 that is a built-in option on several cloud-computing platforms including Google Earth Engine,

345 Functional Data Analysis has received relatively little attention in the remote sensing community

346 (but see *Zhao et al., 2009*; *Yu et al., 2010*; *Acar-Denizli et al., 2018*). Our results show that

347 predictive performance of FLR is comparable to or better than RFR.

348 We note that accuracy of RFR could be improved if we had used all available pixels in the

349 training datasets. Importantly, this would have come at the cost of computational time. Because

350 of our smaller dataset, it is difficult to make broad statements about the relative performance of

351 RFR versus FLR. However, we are cautiously optimistic about the potential of FLR in remote

352 sensing (and precision agriculture), and it deserves more consideration for a few reasons. First,

353 FLR was computationally much faster than RFR and resulted in similar inferences to the widely

354 used linear regression model. This could permit much more rapid modelling of yield using the

355 large data sets that will be necessary to capture geographic variation in the yields across broad

356 geographic areas. Second, all remote sensing time series are functional datasets—data in a form

357 of function—as they provide spectral responses of an object over time (i.e., are functions of

358 time). Thus, FLR (and more generally FDA with a scalar response) are from first principles an

359 ideal tool for the analysis of remote sensing data, because these models can integrate the spectral

360 state of an object over time and relate this to a single response value. In our study, this response

361 was the crop yield measured at a pixel, which is likely to be the product of plant health

362 conditions that vary continuously throughout the growing season, and therefore have the

363 potential to be captured by a function of the spectral state of that pixel over time.

364 # 5. Conclusion

365 Here we presented a simple method to predict precision crop yield using a Sentinel-2 time series

366 and a reference dataset recorded by a Case IH combine yield monitor. We examined two

367 methods of using time series images: using statistical features in a Random Forest Regression

368 and analyzing the spectral time series in a Functional Linear Regression. Results from both

369 modeling approaches indicated that we can predict precision canola yield quite accurately from

370 space. Mean-absolute-errors of all scenarios range from 300 to 390 kg/ha, equivalent to 12.6%-

371 15.5% of the corresponding median values. The spatial distribution of crop yield within the field

372 was also captured in predicted yield maps. Our study is among the first attempts to demonstrate

373 the capability of the medium-resolution multispectral data in mapping precision crop yield.

374 Predicted yield maps can likely be improved in future studies by using a larger reference dataset

375 or incorporating ancillary data such as soil moisture, climatic conditions, crop variety or

376 agriculture practices, although this additional data collection burden might not be desirable when

377 prediction across large geographic areas is the objective. Nonetheless, our findings underline that

378 using medium-resolution multispectral satellite data in precision agriculture research and

379 applications is promising. In this study, we also offer a way to leverage a rich dataset from

380 combine harvester yield monitors to understand crop growth better at both field-level and

381 regional-level. At the field-level, we can identify patches of low and high yields. This

382 information is important for optimizing the productivity of farming operations, and could

383 potentially be used in other applications, such as crop insurance adjustment. At a broader scale,

384 precision yield maps can be created at the township or regional level to provide vital information

385 for food security, agricultural management, and policymaking.

495 **# Appendix**

496 *A – NDVI time series filtering*

497 At any particular location (pixel), let X be a vector containing n values of days-of-year (DOYs)

498 and Y be a vector containing n values of the GEE-retrieved NDVI observed at DOYs in X.

499 **Rule 1:** If a large change in NDVI is detected within a searching window of 14 days, a pixel is

500 considered as cloud contaminated.

501 We define ΔY—an $n \times n$ matrix containing distances between a particular Y value and all values

502 in the Y vector ($\Delta Y_i = y_i - Y$ with i indicates a value position in X, Y vectors and a row position

503 in ΔY). At a random position j, we split ΔY_j into two part: ΔY_{j1} — distances between y_j and Y

504 values to the left of j (start $\rightarrow j$), and ΔY_{j2} — distances between y_j and Y values to the right of j

505 position in Y ($j \rightarrow$ end).

506 If $\min(\Delta Y_{j1}) < -0.1$ & $\min(\Delta Y_{j2}) < -0.1$ & $(\min(\Delta Y_{j1}) + \min(\Delta Y_{j2})) < -0.3$, we conclude that the

507 NDVI observation at j is contaminated by cloud.

508 **Rule 2:** If a very large change in NDVI is detected between three consecutive valid observations

509 (no matter how far they are from each other in terms of DOY), a pixel is considered as cloud

510 contaminated.

511 Let x_1, x_2, x_3 be three consecutive DOYs with GEE-filtered NDVI observations—y_1, y_2, y_3.

512 If $(y_1-y_2) \geq 0.15$ & $(y_2-y_3) \leq -0.15$ & $(y_1+y_3) \geq 0.35$, we conclude that NDVI at x_2 is

513 contaminated by cloud.
