12 **Key Points:**

13 • Fossilized anisotropy dominates where lithosphere is old and thick, with deformation of

14 the Gawler Craton from ~1.6 Ga preserved

15 • Asthenospheric shear relating to Australia's fast plate motion dominates where

16 lithosphere is young and thin

17 • Lithospheric thickness variations likely induce further deviations in mantle flow

Abstract

Rapid plate motion, alongside pronounced variations in age and thickness of the Australian continental lithosphere, make it an excellent location to assess the relationship between seismic anisotropy and lithosphere-asthenosphere dynamics. In this study, SKS and PKS shear-wave splitting is conducted for 176 stations covering the transition from the South Australian Craton to eastern Phanerozoic Australia. Comparisons are made with models of lithospheric thickness as well as numerical simulations of mantle flow. Splitting results show uniform ENE-WSW aligned fast directions over the Gawler Craton and broader South Australian Craton, similar to the orientation of crustal structures generated during an episode of NW-SE directed compression and volcanism ~1.6 billion years ago. We propose that heat from volcanism weakened the lithosphere, aiding widespread lithospheric deformation, which has since been preserved in the form of frozen-in anisotropy. Conversely, over eastern Phanerozoic Australia, fast directions show strong alignment with the NNE absolute plate motion. Overall, our results suggest that when the lithosphere is thin (<125 km), lithospheric contributions are minimal and contributions from asthenospheric anisotropy dominate, reflecting shear of the underlying mantle by Australia's rapid plate motion above. Further insights from geodynamical simulations of the regional mantle flow-field, which incorporate Australian and adjacent upper mantle structure, predict that asthenospheric material would be drawn in from the south and east towards the fast-moving continental keel. Such a mechanism, alongside interactions between the flow field and lithospheric structure, provides a plausible explanation for smaller-scale anomalous splitting patterns beneath eastern Australia that do not align with plate motion.

Plain Language Summary

The Australian continent is moving rapidly northwards at around 7-8 cm per year. As the continent moves it is expected to shear or deform the warmer and weaker layer of the Earth below, called the mantle. The actual pattern of deformation within the mantle can be investigated by studying how seismic waves are polarized as they pass through this material. Results show that for one of the geologically oldest regions in Australia, an area in South Australia, that the deeper part of the continent here was substantially deformed 1.6 billion years ago. This deformation was likely aided by volcanism that occurred at the same time that would have warmed and weakened the material making it easier to deform. This material has since cooled and strengthened over time, freezing in
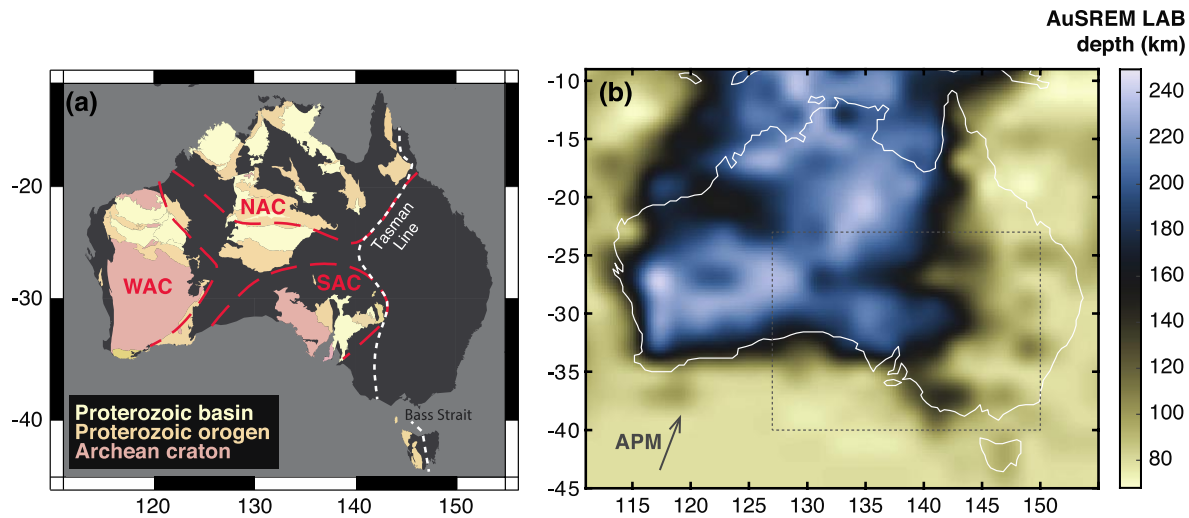

48   the ancient pattern of deformation. Meanwhile in eastern Australia, the continental material here
49   has a much younger geological age (< 550 million years old). The results from this region instead
50   show agreement with the present-day direction of shear due to the fast northwards motion of the
51   Australian continent, as initially expected.

1 Introduction

53   Seismic anisotropy, the directional dependence of seismic wave velocity, is a powerful
54   property for studying dynamic processes within Earth's interior. When the upper mantle undergoes
55   deformation in the dislocation creep regime, a lattice preferred orientation, (i.e. LPO fabric), is
56   expected to develop in olivine (Nicolas and Christensen, 1987). Under typical upper mantle
57   conditions the fast a-axes of olivine will tend to align with the direction of shear (e.g. Karato et al.,
58   2008; Zhang and Karato, 1995) . Using seismic waves that pass through the upper mantle, the
59   geometry and strength of anisotropy can be measured, and inferences drawn on the pattern of
60   mantle flow. Seismic anisotropy, therefore, provides an excellent observation-based constraint on
61   mantle convection, particularly for investigations of the relationship between surface plate
62   kinematics and underlying mantle dynamics.

63   Investigations of upper mantle dynamics via seismic anisotropy are, however, not without
64   ambiguity. One additional factor to consider is the potential for frozen-in or fossilized anisotropy
65   within lithospheric mantle. The lithosphere, Earth's stiff outermost layer, should not be actively
66   generating LPO. However, observations suggest it may preserve an olivine LPO fabric that
67   developed either during its formation (e.g. at the mid-ocean ridge), or during past tectonic/orogenic
68   events that could generate lithospheric deformation (e.g. Debayle and Ricard, 2013; Silver, 1996).
69   The ability to constrain the pattern of fossilized anisotropy therefore holds great potential for
70   revealing the behavior and evolution of Earth's lithosphere.

71   The Australian plate provides an excellent testing ground for interactions between seismic
72   anisotropy, mantle dynamics, and the lithosphere-asthenosphere system. Australia is the fastest
73   moving continent on Earth with an absolute plate motion of 7-8 cm per year towards the north-
74   northeast (Kreemer et al., 2014). Such rapid plate motion may exert significant shear on the upper
75   mantle at the base of the tectonic plate (e.g. Debayle et al., 2005). The Australian continental
76   lithosphere also varies substantially both in terms of age and thickness (Figure 1), with likely
77   implications for lithospheric anisotropy.

Figure 1. Overview of the Australian continent indicating (a) the location of cratons, and (b) the variation in lithospheric thickness from AuSREM (Kennett et al., 2012). The oldest Precambrian provinces of Australia from Raymond et al., (2018) are highlighted in beige and pink colours in (a). The inferred boundary between Precambrian and Phanerozoic Australia, often referred to as the Tasman Line (Direen and Crawford, 2010), is indicated by the dashed white line. The approximate extent of the West Australian Craton (WAC), North Australian Craton (NAC), and South Australian Craton (SAC) is outlined in red. The dotted grey box in (b) indicates the study area shown in Figures 2-3. The small black arrow represents the absolute plate motion (APM) vector of the Australian plate from Kreemer et al., (2014).

In addition to varying contributions of lithospheric anisotropy, the existence of lithospheric steps and substantial 3D topography on the lithosphere-asthenosphere boundary (LAB) likely induces deviations of the upper mantle flow-field as the uneven basal topography of the plate traverses the underlying asthenosphere (Rawlinson et al., 2017). Small-scale convective flow patterns induced by various LAB geometries can be predicted by geodynamic modelling (Duvernay et al., 2021; Farrington et al., 2010), but remain strongly sensitive to uncertain lithospheric structure and uppermost mantle rheology. Nonetheless a number of recent studies have started to link variations in lithospheric thickness/architecture beneath Australia with important and varied surface processes, including Cenozoic volcanism (Davies and Rawlinson, 2014; Rawlinson et al., 2017), the localization of critical mineral deposits (Hoggard et al., 2020),

99 dynamic topography (Ball et al., 2021), and intra-plate seismicity (Bezada and Smale, 2019).

100 Upper mantle anisotropy is typically studied either by surface wave tomography or shear-
101 wave splitting methodologies. Globally the inferences from surface waves and shear-wave
102 splitting tend to agree (Wüstefeld et al., 2009). However, this has not been the case in Australia.
103 Surface wave studies tend to see a strong signal in both azimuthal and radial anisotropy at the base
104 of the continental lithosphere, with fast directions aligned with absolute plate motion (APM) and
105 the expected shear of the underlying asthenosphere (Debayle et al., 2005; Debayle and Ricard,
106 2013; Fichtner et al., 2010; Fishwick et al., 2008; Simons et al., 2002; Yoshizawa, 2014;
107 Yoshizawa and Kennett, 2015), although not all models agree (e.g. de Laat et al., 2023).
108 Conversely, shear-wave splitting studies using core-refracted phases, such as *SKS*, have typically
109 not detected plate-motion aligned fast directions (e.g. Heintz and Kennett, 2006).

110 The number of previous shear-wave splitting studies across Australia (~10) is relatively
111 limited compared to other continental landmasses. Previous authors have typically reported either:
112 (i) weak splitting (i.e. many null measurements or small delay times) (Ba et al., 2023; Chen et al.,
113 2021; Eakin et al., 2021; Heintz and Kennett, 2005; Özalaybey and Chen, 1999; Vinnik et al.,
114 1992); (ii) complex patterns such as frequency dependence of the splitting parameters (Clitheroe
115 and van der Hilst, 1998; Özalaybey and Chen, 1999); or (iii) variability of the retrieved splitting
116 parameters at a given station (Bello et al., 2019; Birkey and Ford, 2022; Chen et al., 2021; Heintz
117 and Kennett, 2006, 2005). Various interpretations have been proposed to explain such results,
118 including: (i) a lack of azimuthal anisotropy present in the upper mantle (Chen et al., 2021;
119 Özalaybey and Chen, 1999); (ii) apparent isotropy due to two anisotropic layers with orthogonal
120 fast directions (Heintz and Kennett, 2006); (iii) contributions from frozen-in lithospheric
121 anisotropy but without clear correspondence to structural trends at the surface (Bello et al., 2019;
122 Birkey and Ford, 2022; Clitheroe and van der Hilst, 1998; Heintz and Kennett, 2005); or (iv) the
123 possibility of asthenospheric flow that is not aligned with the APM, such as around a continental
124 root (Ba et al., 2023; Clitheroe and van der Hilst, 1998; Heintz and Kennett, 2005).

125 Most previous shear-wave splitting studies in Australia had ≤35 stations available, often
126 sparsely distributed on a continental scale, making it difficult to pin-point the cause and location
127 of spatial variations in anisotropy. The first exception is the study of Heintz and Kennett (2005),
128 which had a large number of stations (>100) but was hindered by unusually short recording times

129 (average <6 months), and, therefore, a restricted number of events. The second exception is a
130 recent study by Ba et al. (2023) who reported shear-wave splitting results from 116 stations across
131 the continent with spatially complex patterns. Unlike previous studies, Ba et al. (2023) were able
132 to identify certain locations, such as the peripheral areas of the continent, where the splitting
133 pattern matched well with the direction of absolute plate motion. Overall, they attributed their
134 results to asthenospheric mantle flow with possible (yet unquantified) lithospheric contributions.

135 Recent results from the BILBY north-south transect (Eakin et al., 2021), however,
136 identified a clear correspondence between the splitting fast axis and prominent structural/gravity
137 trends across the South and North Australia Cratons, as well as the suture zone in-between. This
138 provided strong evidence that the shear-wave splitting results in this particular cratonic region are
139 predominantly reflecting lithospheric frozen-in anisotropy rather than asthenospheric
140 contributions. All BILBY stations, however, were located on thick cratonic lithosphere, and so the
141 question of variable lithospheric contributions could not be assessed.

142 In this study we aim to utilize a compilation of over 170 stations that traverse the region
143 extending from thick cratonic lithosphere beneath the South Australia Craton to thinner
144 Phanerozoic lithosphere towards the east. The study is supported by our two recent deployments
145 in South Australia that provide unprecedented coverage of the eastern Gawler margin and South
146 Australian Craton (Eakin, 2019; O'Donnell et al., 2020). Using new data and shear-wave splitting
147 measurements from across these seismic networks we can determine, in detail, how variations in
148 lithospheric thickness and architecture exert a first order control on the pattern of seismic
149 anisotropy and upper mantle dynamics beneath Australia.

150 **2 Tectonic Overview**

151 A large difference in age exists between the western two-thirds of Australia, which is of
152 Precambrian/Proterozoic origin, and the eastern Phanerozoic margin. Precambrian Australia
153 consists of three main crustal components: the North, South, and West Australia Cratons (Figure
154 1a). These are thought to have existed since ~1.8 Ga and were assembled by 1.3-1.1 Ga, during
155 the Rodinia supercontinent cycle, to form proto-Australia (Betts and Giles, 2006; Myers et al.,
156 1996). In contrast, the eastern third of Australia can be described as a series of accretionary or
157 orogenic belts, added to the eastern margin of proto-Australia during the Cambrian to Triassic

158   periods (~550-220 Ma) via subduction (e.g. Glen, 2005). The geological boundary demarcating
159   cratonic Precambrian Australia from eastern Phanerozoic Australia is sometimes referred to as the
160   Tasman Line (Direen and Crawford, 2003) (Figure 1). The precise location of the Tasman Line,
161   inferred from various geophysical and geological observations is, however, often poorly
162   constrained, especially in regions of thick sedimentary cover such as beneath the Lake Eyre region
163   (Agrawal et al., 2022). Nonetheless, it is clear from Figure 1b that western Precambrian Australia
164   is generally underlain by thick lithosphere (>150 km), whereas eastern Australia is characterised
165   by relatively thin continental lithosphere, typically ~75 km thick (Fishwick et al., 2008; Kennett
166   and Salmon, 2012).

167   Our study area covers most of the South Australian Craton, the core of which is composed
168   of the Archean-Proterozoic Gawler Craton and the Proterozoic Curnamona Province (Figures 1-
169   2). The Gawler Craton is the oldest and largest geological province in South Australia and
170   preserves a complex tectonic history spanning from 3200 Ma to 1450 Ma (Myers et al., 1996). The
171   Archean and Paleoproterozoic core of the Gawler Craton forms a folded belt that underwent
172   deformation along discrete shear zones during the Mesoproterozoic (Hand et al., 2007).
173   Throughout the Proterozoic, the region saw multiple major magmatic events, recorded in the
174   geological record by the Donington Suite (ca. 1850 Ma), St. Peter Suite (1620 to 1610 Ma), and
175   Gawler Range Volcanics-Hiltaba Suite (1595 to 1575 Ma) (Hand et al., 2007).

176   **3 Data and Methods**

177   3.1 Station and event availability

178   In total 176 stations in Australia were analysed for *SKS* and *PKS* splitting in this study. The
179   distribution of these stations covers a wide area including the South Australia Craton (Gawler and
180   Curnamona Provinces), as well as Phanerozoic regions to the east and south-east (Figure 2a). Two
181   new seismic deployments in South Australia provide increased station coverage over the eastern
182   Gawler Craton (yellow and green symbols in Figure 2a). The first of these deployments is the Lake
183   Eyre Basin Seismic Array (Network: 5G), including 22 broadband stations deployed in the region
184   surrounding Kati Thanda-Lake Eyre (Eakin, 2019). Instruments were installed in several phases
185   between September 2018-October 2019, and remained in-place until July 2022. Several data gaps
186   exist, including the period from June-October 2020 resulting from COVID-19 related state border

187   closures and travel restrictions that prevented servicing of the network. A second array, AusArray-

188   SA (Network: 6K), was deployed south of the Lake Eyre Basin array by the Geological Survey of

189   South Australia (O'Donnell et al., 2020). This consisted of 38 broadband stations that operated

190   over a similar timeframe from October 2020 to June 2022.

191

192

193   **Figure 2**. Map showing distribution of (a) seismic stations, and (b) earthquakes used in this study.

194   The dashed black line in (a) indicates the approximate position of the Tasman Line for this region.

195   The outline of the Gawler Craton and Curnamona (Cu) province are shown in grey. The event map

196   presented in (b) shows the typical event distribution at one station, OOD, the location of which is

197   highlighted in (a) in cyan. Events are plotted as open circles colour-coded by those that produced

198   a splitting measurement (green), and those that did not (black).

199

200   The station coverage is supplemented by data from two permanent national networks.

201   These include 23 stations from the Australia National Seismic Network (red symbols in Figure 2a,

202   Network: AU) and 17 stations from the Australian Seismometers in Schools (AuSiS) program

203   (blue symbols Figure 2a, Network: S1). The remaining 76 stations (black symbols) represent a

204   compilation of 8 past temporary broadband deployments. Most of these sites operated for 12-24

205   months. A full list of all temporary (and permanent) networks is provided in the data availability

206   section. The majority of these sites have not been previously analysed for *SKS* splitting. Those that

207 have are re-analysed to ensure consistency in the methodology across the region. The only

208 exceptions are results from the BILBY array (stations BL:15, 16, 17, 19, 20, 24) and permanent

209 station AU:MULG from our earlier study of Eakin et al., (2021). This study followed the same

210 methodology as is applied here and therefore these results are directly included in the dataset

211 without re-processing.

212   For event selection, earthquakes of magnitude 6.0 and above were utilised in the epicentral

213 distance range 90°-130° for *SKS* and 130°-150° for *PKS* phases (Figure 2b). This equates to around

214 30-40 events per year for a seismic station in southern Australia. While events originate across a

215 range of backazimuths they are most plentiful from the South America subduction zone from the

216 south-southeast direction (Figure S4).

217 3.2 Shear-wave splitting processing and methodology

218   Shear-wave splitting analysis was undertaken using the SplitLab software package

219 (Wüstefeld et al., 2008). Multiple methods for estimating the best-fitting shear-wave splitting

220 parameters (the fast direction: Φ and delay time: δt) are available within the SplitLab

221 environment. For quality control purposes we compare estimates from two independent

222 methods. The first is the rotation correlation (RC) method (Bowman and Ando, 1987), which

223 determines the values of Φ and δt, which generate the maximum cross-correlation between the

224 trial fast and slow components. This method can produce systematic error as a function of

225 initial polarisation, or as a function of backazimuth for *KS* phases (Eakin et al., 2019;

226 Wüstefeld and Bokelmann, 2007). When the initial polarisation approaches the fast or slow

227 orientation of the anisotropic medium the RC method will predict a best fitting value of Φ that

228 deviates 45° from the true value, with a delay time that is close to zero (e.g. Figure S9). While

229 such systematic measurement error is not ideal, it is well understood and predictable. With

230 this in mind, the true splitting parameters can still be easily retrieved from this method (Eakin

231 et al., 2019).

232   The second method is the transverse energy minimisation (SC) method (Silver and

233 Chan, 1991). Using this method, we seek those values of Φ and δt that best minimise the

234 energy on the transverse component, following a correction for shear-wave splitting. The SC

235   method is thought to produce more stable *SKS* splitting measurements over a wider range of

236   backazimuths. However, it can also be susceptible to the same systematic error as seen for the

237   RC method when the signal-to-noise ratio is moderately high (Eakin et al., 2019; Wüstefeld

238   and Bokelmann, 2007). Unlike the RC method, the SC method is dependent on the estimated

239   initial polarisation. The quality of results from the SC method is therefore particularly

240   sensitive to any misalignment of the station orientation and/or miscalculation of the back-

241   azimuth (Eakin et al., 2018). For these reasons, and unless otherwise specified, the results

242   presented in the following sections are from the RC method.

243   Quality control procedures followed our previous work (Eakin et al., 2021, 2019,

244   2015) including visual inspection of all waveforms and strict quantitative and qualitative

245   criteria. Further details of the criteria used to determine whether a split (or null) measurement

246   was of acceptable quality are provided in the supplementary text. As an initial step,

247   waveforms were filtered between 0.04-0.125 Hz using a Butterworth bandpass filter. Any

248   event with a signal-to-noise ratio (SNR) of less than 5 for the *SKS*/*PKS* phase was discarded.

249   Using this initially curated dataset, a station misalignment value was estimated. This estimate

250   follows similar investigations by Eakin et al., (2018), that measured the difference between

251   the initial polarisation of *SKS*/*PKS* phase (as determined from the orientation of the

252   uncorrected particle motion) and the source-receiver backazimuth. If the station is found to be

253   misaligned with north then the appropriate orientation correction is applied to all waveforms

254   before further analysis. Station misalignment values applied in this study are available in

255   Table S1.

256   To help identify regional variations in shear-wave splitting patterns, a stacked result

257   was calculated for each station that had multiple measurements. This was estimated by

258   stacking of the RC error-matrices from all individual split measurements. The station average

259   Φ and δt values are then found from the global minimum of the stacked error surface (Wolfe

260   and Silver, 1998). A further check is performed between the stacked δt result and the mean δt

261   from the individual measurements with a ratio of <1.75 required. This ensures that the stacked

262 splitting results presented in the final dataset are consistent with the average properties of the
263 individual measurements.

264 3.3 Mantle flow modelling

265   We build on the models developed by Davies et al., (2019) to generate a synthetic mantle
266 flow field for comparison with seismic anisotropy observations. Although we focus on the
267 Australian region, our model is global. We solve the equations governing incompressible mantle
268 convection inside a spherical shell, using Fluidity (Davies et al., 2011; Kramer et al., 2012). In
269 our simulation, the inner radius corresponds to the Core Mantle Boundary (CMB) and the outer
270 radius to Earth's surface. Free-slip mechanical boundary conditions are specified at the CMB,
271 with present-day plate kinematics from Müller et al., (2016) prescribed at the surface. Our mesh
272 is generated by refining an icosahedron, resulting in a lateral resolution of 50 km at the surface.
273 This mesh is extruded in the radial direction, with radial spacing increasing linearly from 10
274 km at the surface to 100 km at the CMB.

275   We determine the present-day density and temperature fields by adopting a robust
276 thermodynamic approach for converting between seismic and physical structure. This approach,
277 described in Ghelichkhan et al., (2021), uses the upper mantle tomography model of de Laat et
278 al., (2023) above 300 km depth, transitioning smoothly to the whole mantle shear-wave
279 tomography model of S40RTS (Ritsema et al., 2011) for depths below. The former provides
280 higher resolution on lithospheric structure owing to the sensitivity of surface waves. We use
281 Perple_X (Connolly, 2009) alongside the thermodynamic database of Stixrude and Lithgow-
282 Bertelloni (2011) to determine equilibrium phase assemblages throughout the mantle as a
283 function of temperature, and pressure, and their associated anharmonic V_S and density values
284 for pyrolytic mantle. To account for anelastic effects, anharmonic V_S is corrected using an
285 updated version of the Q_5 model by Cammarano et al., (2003). We employ a temperature- and
286 depth-dependent viscosity field, with parameters that are identical to those of Davies et al.
287 (2023), constructed to be compatible with observations of Earth's geoid, heat flux, post-glacial
288 rebound, and CMB ellipticity.

289 **4 SKS & PKS splitting results**

290   Overall, our splitting analysis yielded 1207 measurements across 157 stations, all of which

291   were individually and visually inspected. A full list is provided in Supporting Information Table

292   S1 in the supporting information. While a single measurement by itself can be unreliable, 67

293   stations had multiple non-null measurements that produced a stacked splitting result (Figure 3).

294   By utilizing this smaller curated dataset, we focus our attention on those stations with the most

295   robust results. In general, the pattern of individual measurements across all the stations in the study

296   area agrees well with the pattern retrieved from these stacked station results (Figure S2).

297

298

Figure 3. Stacked *KS* splitting results for stations across the study region plotted against (a)
surface elevation, and (b) an estimate of lithospheric thickness from AuSREM (Kennett et al.,
2012). The stacked splitting parameters for each station are represented by coloured bars,

302   orientated according to the fast direction, and scaled in length by the delay time. In (a) the bars are

303   coloured according to the fast direction, as indicated by the corresponding colour bar. In (b) colours

304   represent the misfit between the fast direction and the absolute plate motion (APM).

305

306   Considering the map of stacked split results in Figure 3a, a broad similarity of splitting

307   parameters can be seen between neighbouring stations indicating a spatially coherent source of

308   seismic anisotropy below. Throughout the Gawler and South Australian Craton there exists a

309   strikingly consistent ENE-WSW splitting pattern (pink/red bars in Figure 3a). The average fast

310   direction (Φ) for the 22 stations within the Gawler Craton is 70°, and 0.80 seconds for the delay

311   time (δt). This is in agreement with our previous study of permanent station MULG (Φ: 79°, δt:

312   1.1 s) located within the Gawler Craton (Eakin et al., 2021). Other recent studies have reported a

313   similar NE-SW to ENE-WSW trend over the South Australian Craton (Ba et al., 2023; Birkey and

314   Ford, 2022). The spatial extent of this shear-wave splitting pattern, throughout the Gawler Craton

315   and extending eastwards into the Curnamona Province, can now however be seen more clearly.

316   Beyond the craton margins the pattern changes slightly. To the craton's northwest there are only a

317   handful of stations, but these show a change to WNW-ESE fast directions (yellow/orange bars

318   Figure 3a). To the north of the Gawler Craton, over the Lake Eyre region, the fast direction rotates

319   slightly to become more north-easterly (purple coloured bars Figure 3a).

320   The most notable change is seen crossing from western cratonic Australia into eastern

321   Phanerozoic Australia. The majority of stations in eastern Australia display larger delay times

322   (mean δt: 1.26 s) and N-S to NNE-SSW fast directions (mean Φ: 20°) represented by blue coloured

323   bars in Figure 3a. This orientation is very similar to the absolute plate motion (APM) of the

324   Australian plate, ~6 cm/year at 21° (clockwise from North) in this location, as indicated by the

325   black arrow in Figure 3. Hints of such a correspondence between the fast direction and the absolute

326   plate motion for eastern Phanerozoic Australia have been previously noted based on more limited

327   results (Ba et al., 2023; Bello et al., 2019; Birkey and Ford, 2022). The results of our analysis

328   confirm a similarity between the splitting fast direction and the absolute plate motion for

329   southeastern Australia that is spatially distinct from the pattern over cratonic Australia.
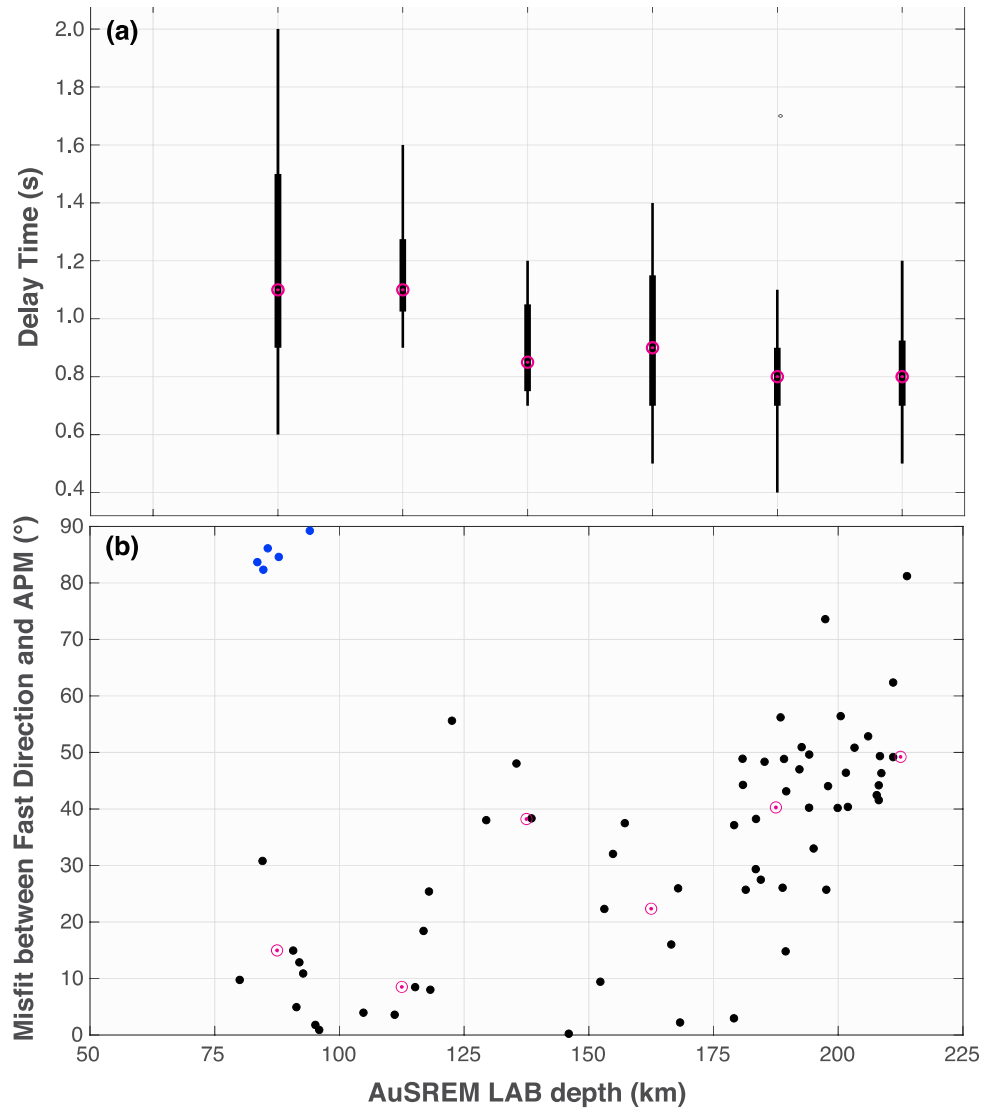

330   Interestingly, there is a small cluster of five stations in the very south-eastern corner of

331   Australia (~ latitude: 37°S, longitude: 148°E) that show a contrasting but consistent ESE-WNW

332   orientation (ave Φ: -76°, δt: 1.0 s) as indicated by the cluster of orange bars in Figure 3a. Some of

333   these same stations have been previously analysed in other studies: results from Ba et al., (2023)

334   indicated a similar pattern for this sub-group of stations, however the pattern from Bello et al.,

335   (2019) was less spatially consistent.

336   4.1 Comparison with lithospheric thickness

337   Across the study region, lithospheric thickness reduces drastically from west to east (Figure

338   1b). Beneath the Gawler and South Australian Craton, where the splitting fast directions are

339   consistently ENE-WSW the lithosphere is ~ 200 km thick (Figure 3b). Over eastern Phanerozoic

340   Australia, where stations show a strong similarity between the fast direction and absolute plate

341   motion (indicated by red bars in Figure 3b), the lithosphere is much thinner with a typical LAB

342   depth ~70-100 km.

343   A direct comparison of the splitting parameters against LAB depth is plotted in Figure 4 to

344   better quantify this observation. Across the study region we find that the average delay time

345   decreases as the LAB deepens (Figure 4a). This varies from δt >1.0 seconds when the LAB is

346   shallower than 125 km, to an average delay time of ~ 0.8 seconds when the LAB depth is > 175

347   km. Correspondingly the misfit between absolute plate motion and the fast splitting direction is

348   <20° for most stations located where the LAB depth is <125 km (Figure 4b). The cluster of blue

349   points in Figure 4b that defy this relationship correspond to the anomalous cluster previously

350   identified in the southeastern corner of Australia (i.e. blue bars Figure 3b). For LAB depths greater

351   than 150 km, the misfit between the splitting fast direction and absolute plate motion tends to grow

352   as the lithosphere gets thicker.

353   There are a small handful of stations with stacked splitting results that fall along the edge

354   of the thick cratonic lithosphere as it transitions to thinner lithosphere. These stations tend to show

355   fast directions that are approximately parallel to the general geometry of the lithospheric step, such

356   as those that fall within the white-dotted band in Figure 3b.

Figure 4. Graph illustrating the relationship between splitting parameters and lithospheric thickness, using the data illustrated in Figure 3b. Median values for each bin are indicated by pink circles. The 5 blue dots in (b) correspond to the cluster of stations in southeast Australia in Figure 3b where results were plotted in the same shade of blue.

4.2 Comparison with the predicted mantle flow field

Uppermost mantle structure and lithospheric thickness variations beneath Australia will influence the underlying asthenospheric flow regime. Geodynamical models that incorporate such upper mantle structure can provide insights on what dynamic processes may be occurring, helping to inform shear-wave splitting observations. In Figure 5 our splitting observations are compared

368   to predictions across the region from a mantle flow simulation (as outlined in Section 3.3). Where

369   the inferred upper mantle viscosity is high at 200 km depth (indicative of the lithosphere), the

370   predicted flow field (small black arrows in Figure 5) generally aligns with absolute plate motion,

371   as prescribed at the surface, demonstrating rigid plate motion within the high viscosity lid. The

372   observed ENE-WSW oriented splitting pattern over this region of high viscosity is therefore

373   inconsistent with the present-day mantle flow direction predicted in our simulation.

374

375

376   **Figure 5.** Results of mantle flow simulations at (a) 120 km, and (b) 200 km depth. Stacked *KS*

377   splitting results (same as Figure 3) are plotted in yellow and compared to mantle viscosity and

378 flow vectors (tangential velocities indicated by small black arrows). Further details for the mantle

379 flow simulation are provided in section 3.3, as well as plots of viscosity and radial velocity at

380 various upper mantle depths in Figure S5.

381

382   At the same depth, beneath eastern Australia, the mantle viscosity is predicted to be lower

383 (Figure 5), reflecting the presence of thinner lithosphere and shallower asthenospheric material. In

384 this region the predicted mantle flow-field has a greater E-W component, with mantle material

385 from the east being drawn in towards high-viscosity thick lithosphere in the west and rotating to

386 align with plate motion upon interaction with lithospheric structure. In the simulation, as the

387 Australian continent moves rapidly northwards, the motion of the cratonic lithosphere through the

388 upper mantle creates a region of lower pressure, with lower viscosity asthenospheric material from

389 surrounding areas drawn towards this region. This westwardly flow is strongest in the model in

390 the south-east corner of the study region, matching well (particularly at 200 km depth, Fig. 5b)

391 with the sub-group of 5 stations that showed anomalous ESE-WNW orientated splitting (orange

392 bars in Fig. 3a). In general, however, the shear-wave splitting pattern over eastern Australia shows

393 a greater similarity to the absolute plate motion, rather than the asthenospheric flow-field predicted

394 in the mantle flow simulation.

5 Discussion

396   Our results demonstrate clear and spatially coherent shear-wave splitting patterns (Figures

397 3-4). This splitting pattern appears to morph from an ENE-WSW alignment over the thicker

398 lithosphere of the South Australian Craton, to a NNE-SSW alignment, that follows the APM for

399 stations located above the thinner Phanerozoic lithosphere in the east. This clear pattern is in

400 contrast to the weak splitting and complex anisotropy often inferred by the earliest studies of *SKS*

401 splitting in Australia (e.g. Clitheroe and van der Hilst, 1998). Further context regarding the

402 emergence of coherent seismic anisotropy beneath Australia can be found in the supplementary

403 text (section ST2). As is common practice for **KS* splitting studies at the continental scale (e.g.

404 Ba et al., 2023; Eakin et al., 2010), we have presented stacked splitting results at each station. Such

405 stacked results allow for interpretation in terms of a single (and relatively simple) layer of

406 anisotropy. Analysis of the back-azimuthal variations lends support to such a single-layer

407 interpretation (Figures S9-S10), and we find that complex or multi-layered anisotropy is not
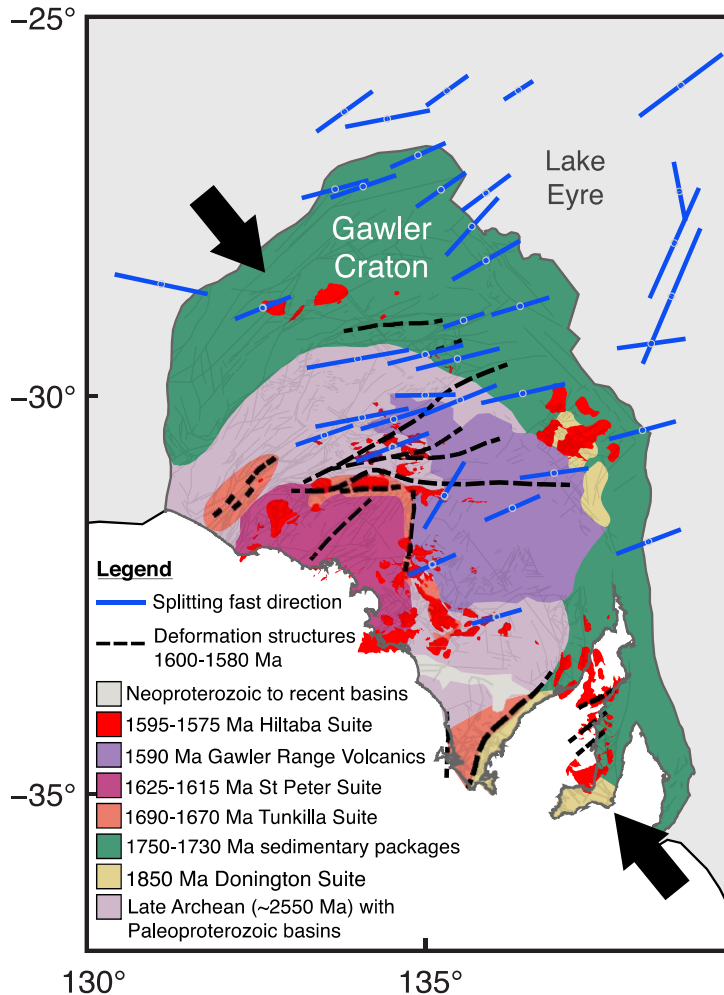

408   required to explain the results (refer to section ST3 of the supplementary text for extended details).

409   5.1 Anisotropic Contributions from the Lithosphere versus Asthenosphere

410   Placing the results into the context of simple (i.e. single-layer) anisotropy allows for a
411   straightforward interpretation, that is consistent with geological constraints. The relationship
412   between lithospheric thickness and alignment of the fast direction with the absolute plate motion
413   (Figures 3-4) can be easily explained. Where the lithosphere is relatively young and thin (<100 km
414   thick) over eastern Phanerozoic Australia (Figure 3) the contribution from lithospheric anisotropic
415   fabrics is likely small. Instead, the anisotropic signal from the asthenosphere can dominate,
416   resulting in splitting fast directions that match with the absolute plate motion (Figure 3). This
417   suggests shear of the underlying mantle asthenosphere by the fast plate motion above, as has long
418   been proposed by surface wave studies that imaged strong APM aligned azimuthal anisotropy at
419   the base of the plate (e.g. Debayle et al., 2005).

420   Conversely where the lithosphere is relatively old and thick (>175 km thick) over cratonic
421   Precambrian Australia (Figure 3), the consistent ENE-WSW orientations suggests that anisotropic
422   contributions from fossilized lithospheric fabrics dominate the shear-wave splitting signal. This is
423   not to say that strong shear of the asthenosphere below is no longer occurring (as has been imaged
424   by surface waves), but that the shear-wave splitting appears most sensitive to shallower
425   lithospheric anisotropy in the mantle's uppermost 200 km. Such an observation is supported by
426   previous modelling of vertically varying anisotropy and synthetic seismograms by Saltzer et al.,
427   (2000). Their work suggested that *KS* splitting measurements may be more biased towards the
428   upper portion of the anisotropic medium with the greatest sensitivity at around one-third of the
429   depth of the total extent of the anisotropy. They suggest that this explains why many stable
430   continents display fast splitting directions that mirror surface geology (e.g. Silver, 1996), which is
431   also the case here (Figure 6).

432   The reduced delay times (< 1 second) for stations situated on-top of thick lithosphere
433   (Figure 4a) however would suggest that when the primary source of anisotropy is from the
434   lithosphere, this is not as strong as when the lithosphere is thin (< 125 km) and the primary source
435   is more likely from asthenospheric flow. Alternatively, when the lithosphere is thick and
436   lithospheric contributions dominate, a more minor but opposing contribution from the deeper
437   asthenosphere could cause a slight reduction of the delay times.

438

Figure 6. Comparison of stacked *KS* splitting results (blue bars) with a simplified geological map of the Gawler Craton, modified from Hand et al., (2007). Location of crustal deformation structures are shown (thick dashed black lines) that either formed or reactivated during NW-SE directed compression (as indicated by the large black arrows) during the interval 1600-1580 Ma. The similar pattern of Archean-Early Mesoproterozoic faults (thin grey lines), as well as coeval volcanism from the Hiltaba Suite (red polygons), are overlain from Cowley, (2006).

Considering that the splitting pattern changes drastically from west to east across the study area, the most plausible explanation appears to be a change in the primary source of anisotropy from lithospheric to asthenospheric. In Australia, studies of azimuthal anisotropy from surface waves also tend to show clear east-west trending fast axes at lithospheric depths (~ 50-150 km) within the South Australian Craton (e.g. Fishwick et al., 2008; Simons et al., 2002). Moving

451 eastwards as the lithosphere thins, these fast axes tend to change orientation within the same depth

452 slice (e.g. Figure S7), but it is difficult for surface waves to delineate lateral contrasts in seismic

453 anisotropy. In contrast, Quasi-Love wave scatterers, which are sensitive to lateral gradients in

454 seismic anisotropy at upper mantle depths (~100-200 km) (Eakin, 2021), can often be traced to the

455 edge of thick lithosphere and to locations where a change in our shear-wave splitting pattern occurs

456 (Figure S6).

457 5.2 Implications for the South Australian Craton

458 Over the South Australian Craton, which encompasses the Archean-Proterozoic Gawler

459 Craton and Curnamona Province, the *KS splitting displays a consistent ENE-WSW orientated

460 pattern (Figure 3a). North of our study area, the orientation of the fast direction has previously

461 been shown to flip to match the NW-SE aligned terrane boundaries within the North Australia

462 Craton (Eakin et al., 2021). This likely indicates that the lithospheric anisotropic fabric differs

463 between the two major cratonic domains, reflecting different tectonic histories.

464 Within the South Australia Craton, upon first impressions, the ENE-WSW orientation of

465 the anisotropy does not appear to match the outline of the major geological provinces or crustal

466 boundaries (Figure S8), as noted by Birkey and Ford (2022). However, upon closer inspection, the

467 ENE-WSW orientated fast directions agree very well with the structural trends found internally

468 within the Gawler Craton, which are preserved as a series of E-W to NE-SW trending faults (Figure

469 6). Several of these major crustal shear zones and deformation structures (highlighted by thick

470 black dashed lines in Figure 6) either formed or were reactivated during the mid-Proterozoic

471 around 1.6 to 1.58 billion years ago (Hand et al., 2007). This time period is associated with the last

472 major deformational event that impacted the entire Gawler Craton, due to large-scale NW-SE

473 directed compression (indicated by the thick black arrows in Figure 6) (Hand et al., 2007). Such a

474 tectonic history is consistent with the anisotropic geometry retrieved by this study. This strongly

475 suggests that the splitting pattern over the Gawler Craton (and surroundings) is a manifestation of

476 fossilised LPO fabrics frozen into the lithosphere and preserved for well over a billion years. The

477 consistency of splitting pattern over such a large area suggests widespread uniform deformation

478 of the lithosphere during the Proterozoic, before it fully cratonized.

479 Intriguingly at the time of deformation, the region also experienced significant volcanism

480 and heating, as recorded by the emplacement of the Gawler Range Volcanics (~1590 Ma) and the

481   Hiltaba Suite (1595-1575 Ma). Both magmatic events impacted large swaths of the Gawler Craton,

482   as indicated in Figure 6. The introduction of heat and melts from this volcanism may have

483   substantially weakened the lithosphere and further aided widespread deformation, producing the

484   significant lithospheric LPO fabrics still seen today. After the emplacement of the Hiltaba Suite,

485   volcanism ceased in the region, allowing the lithosphere to cool, strengthen, and preserve the

486   anisotropy over the following 1.6 billion years.

487   5.3 Deviations of the asthenospheric flow associated with LAB topography

488   While there appears a clear relationship between the splitting parameters and lithospheric

489   thickness (Figure 4), there are some locations where the splitting fast directions neither follow the

490   APM-aligned mantle flow direction nor the inferred orientation of the lithospheric fabric. One such

491   location is along the eastern edge of the thick cratonic lithosphere (highlighted by the dotted white

492   band in Figure 3b). While there are only a small number of stations in this zone, intriguingly the

493   orientation of the fast direction appears to follow the general trend of the lithospheric step, as

494   indicated by the AuSREM LAB model. This perhaps hints at a deviation of the mantle flow field

495   around the edge of the cratonic root. Such a mechanism can be seen in our mantle flow simulations,

496   particularly at 120 km depth along the north-eastern boundary of the higher viscosity region

497   (Figure 5a). However, this location varies with depth in the simulations and is offset further east

498   compared to the lithospheric step suggested by the AuSREM LAB model (Figure 3b). Deviations

499   of flow around the continental keel have been invoked previously to explain departures of the

500   splitting fast direction from the absolute plate motion of Australia (Ba et al., 2023; Bello et al.,

501   2019; Clitheroe and van der Hilst, 1998; Heintz and Kennett, 2005). However, it has not previously

502   been imaged parallel to, and directly in the vicinity of, the lithospheric step as seen in Figure 3b.

503   Alternatively, some of the stations within this band, particularly in the north, match well with the

504   predicted upper mantle flow from our simulation (Figure 5). This suggests that the pattern could

505   also be reproduced by mantle flow drawn in towards the fast-moving continent, rather than flow

506   diverted around the lithospheric step.

507   Another interesting location where the splitting fast direction departs from the general trend

508   of APM alignment is the cluster of results in the southeast corner of the study area, highlighted in

509   blue in Figures 3b and 4. In this region the lithosphere is quite thin (< 100 km), so a substantial

510   contribution from lithospheric fabrics would not be expected. Intriguingly, however, the splitting

511 pattern in this location matches well with the westward directed mantle flow predicted by our
512 geodynamic simulation along eastern Australia, especially at ~200 km depth (Figure 5b). This may
513 suggest that it is the result of a similar process, whereby asthenospheric material from beneath the
514 Tasman Sea is being drawn in towards the higher viscosity lithospheric keel of the Australian
515 continent. Why the process would be localized to just this area remains unclear, but perhaps
516 suggests more complex lithospheric architecture in this region than is presently resolved by
517 tomographic models, such as that by de Laat et al., (2023) utilized here.

518 To the south of this E-W orientated splitting cluster lies a well imaged low velocity
519 anomaly in the shallow upper mantle of the Bass Strait (e.g. de Laat et al., 2023). This low velocity
520 feature has been variously attributed to localized edge-driven convection (Davies and Rawlinson,
521 2014; Rawlinson et al., 2017), and/or a mantle plume (Davies et al., 2015), both of which would
522 induce small-scale deviations of the mantle flow-field. Additionally, strong scattering of Love-to-
523 Rayleigh waves beneath the Bass Strait have been observed (Eakin, 2021), indicative of lateral
524 gradients in upper mantle anisotropy. Together these observations and models suggest small-scale
525 convective processes are likely occurring beneath the Bass Strait that may influence the anomalous
526 patterns of seismic anisotropy beneath southeastern Australia.

6 Conclusion

528 From analyzing *KS* splitting at over 170 stations and focusing on those that could provide
529 high-quality stacked results, coherent but regionally variable anisotropic patterns have emerged
530 beneath south and eastern Australia. In regions of comparatively thin lithosphere (70-125 km), we
531 find fast directions aligned with Australia's rapid plate motion, as predicted from surface wave
532 studies. This demonstrates that lithospheric contributions are minimised beneath eastern Australia,
533 with splitting patterns principally governed by asthenospheric flow. Conversely, where the
534 lithosphere is thicker beneath the South Australian Craton, ancient deformational fabrics appear to
535 dominate that have likely been preserved within the lithospheric mantle. The trend of this
536 anisotropic fabric is comparable with deformational structures from the Early-Mesoproterozoic
537 found within the Gawler Craton. Such findings imply widespread and uniform deformation of the
538 region, coeval with the addition of heat and the emplacement of the Hiltaba Suite and Gawler
539 Range Volcanics, before the South Australian lithosphere cratonized at ~1.6-1.5 Ga.

540 Lithospheric thickness variations therefore appear to exert a first-order control on the

anisotropic signal retrieved from shear-wave splitting beneath Australia. While continental scale imaging of the LAB beneath Australia has been achieved by seismic tomography (e.g. Kennett and Salmon, 2012), it is more difficult to resolve sharp lateral contrasts in lithospheric age and thickness that may demarcate important tectonic boundaries such as the enigmatic Tasman Line. With the ongoing expansion of seismic data collection across Australia, further detailed investigations of the anisotropic structure may therefore hold significant potential for unveiling the expansive tectonic history and lithospheric architecture of this ancient continent.
