Text S1. Methods Supplement. Here we described additional details for the methods used in the main manuscript related to thermal image data processing. The code repository and further documentation are available at https://github.com/colinrr/locust.git.

1. Thermal Imagery Pre-processing

1.1. Data Format Conversion and Frame Registration

The thermal imagery, initially recorded in the propriety InfraTec *.irb* format, were first converted to an ASCII file format using one of two methods: via the Infratec IRB2ASCII executable, or the program IRT_Analyzer. The resulting text files are then converted into MATLAB data format. For a given sequence of thermal image frames, a single *.mat* file

is generated for each frame, as a well as a file containing a table of header information with rows corresponding to each frame, titled *frameHeads.mat*.

Following conversion to MATLAB file format, frame registration is performed as needed when the camera viewfield was not perfectly steady. For instance, wind periodically caused minor shaking of the camera during video recording, which must be corrected to avoid large spatial displacements of imaged objects between frames. Figure S1 shows an example of temperature differences between frames for Event 3 before and after registration. A brief period of strong wind gusts caused significant shaking of the camera, such that temperature differences become large between frames for a given pixel due to the displacement of imaged objects. Re-alignment of these images using the MATLAB image registration package prevents erroneous plume segmentation and velocity analysis during later processing steps.

1.2. Plume segmentation using plumeTracker

To obtain image masks identifying pixels as belonging to an eruption plume, we use the **plumeTracker** software of Bombrun, Jessop, Harris, and Barra (2018), modified to facilitate efficient data input and output in our workflow (the core image segmentation algorithm is unchanged). In most instances, clear skies provided excellent thermal contrast between plumes and the background of thermal images, and **plumeTracker** segmentation was very effective in these instances for producing binary image masks. In instances where clouds are present in the vent region (either atmospheric vapor or outgassing from the vent itself), the **plumeTracker** software struggled to differentiate between cloud and plume motions. In these cases and as necessary, we applied **plumeTracker** to a pre-processed

38 version of the thermal images, in which we enhanced contrast prior to segmentation and/or

39 perform manual masking of image regions in which no plume was present.

1.3. Mapping Pixels to Physical Coordinates

40 To calculate the positions, dimensions, and velocities of image features, it is necessary

41 to obtain estimates of pixel dimensions (in meters) at the target (vent or plume) distance,

42 accounting for the viewing angle of the camera. Figure S2 shows the view geometry and

43 relevant parameters. Here we generate a mapping function that converts pixel coordinates

44 to distances relative to the camera reference frame. Using a modified form of the geometric

45 corrections in Harris (2013, Chapter 9), we first assume that (a) the target plume lies in a

46 2D vertical plane, centered above the vent and horizontally perpendicular to the camera

47 view azimuth (as in Figure S2a), and (b) that only vertical tilt of the thermal images is

48 present, with no horizontal tilt (the camera was leveled during field observations). We

49 further assume that lens distortion is negligible (a correction is applied internally in the

50 camera), such that the thermal images represent an ideal camera perspective projection.

51 We first need the true azimuth, ϕ_0, and elevation angle relative to horizontal, θ_0, of

52 the camera view centerline. Using the geodetic coordinates of the camera observation

53 point, a visible reference point on the Sabancaya edifice, and the estimated vent location

54 (see Figure S2a,c), we calculate the azimuth, elevation angle, and slant distance from the

55 camera observation point to the reference point, $(\phi'_{ref}, \theta'_{ref}, D_{ref})$, and to the Sabancaya

56 vent, $(\phi'_v, \theta'_v, D_v)$. Here the $'$ indicates that angles are *apparent* angles with respect to the

57 camera reference frame (i.e. less than the true angle relative to camera centerline, see Fig-

58 ure S2b). The coordinates of the reference point and vent location are estimated from the

59 ALOS 12 digital elevation model (ASF-DAAC, 2015) and Google Earth satellite imagery.

September 14, 2023, 7:20pm

The angular distance in azimuth and elevation angle between the camera centerline and the reference point are, respectively:

$$d\theta_{ref} = \left[i_{ref} - \left(\tfrac{n_i}{2} + 0.5\right)\right]\beta_i\,, \tag{S.1}$$

$$d\phi_{ref} = \left[j_{ref} - \left(\tfrac{n_j}{2} + 0.5\right)\right]\beta_j\,, \tag{S.2}$$

where $d\theta_{ref}$ and $d\phi_{ref}$ are the angular distances within the camera field of view between the reference point and camera centerline; (i_{ref}, j_{ref}) are the vertical and horizontal pixel coordinates of the reference point in the image, respectively; (n_i, n_j) are the vertical and horizontal image resolution in pixels, respectively; and (β_i, β_j) are the vertical and horizontal angular fields of view for a single pixel. To retrieve the geodetic elevation angle and azimuth, we then apply an apparent angle correction to account for the camera tilt to obtain the camera elevation angle θ_0 and azimuth ϕ_0 (in geodetic reference frame):

$$\theta_0 = \theta_{ref} - d\theta_{ref} = \tan^{-1}\left(\frac{\tan(\theta'_{ref})}{\cos(d\phi_{ref})}\right) - d\theta_{ref}\,, \tag{S.3}$$

$$\phi_0 = \phi'_{ref} - d\phi'_{ref} = \phi'_{ref} - \tan^{-1}\left(\cos(\theta_0)\tan(d\phi_{ref})\right)\,. \tag{S.4}$$

Using a similar apparent angle correction, the horizontal angular distance from camera centerline $d\phi_v$ and elevation angle θ_v to the vent location are given by:

$$d\phi_v = \tan^{-1}\left(\frac{\tan(\phi'_v - \phi_0)}{\cos(\theta_0)}\right)\,, \tag{S.5}$$

$$\theta_v = \tan^{-1}\left(\frac{\tan(\theta'_v)}{\cos(d\phi_v)}\right)\,. \tag{S.6}$$

We then calculate horizontal distance from camera to vent D_x and slant distance from camera to the centerline pixel D_{los} (in the projected vertical plane) according to:

$$D_x = D_v \cos(d\phi_v)\cos(\theta_v)\,, \tag{S.7}$$

$$D_{los} = \frac{D_x}{\cos(\theta_0)}\,. \tag{S.8}$$

September 14, 2023, 7:20pm

81 Once the above calculations are performed for a given camera location, image coordinates

82 i, j in units of pixels may be readily converted to coordinates in meters in the projected

83 image plane (x, z) by:

$$z \qquad = D_x \tan \left[\theta_0 - (i - 0.5 - \tfrac{n_i}{2}) \right] \beta_i \,, \tag{S.9}$$

$$x = (D_{los} + (D_x \tan(\theta_0) - z) \sin(\theta_0)) \tan \left[(j - 0.5 - \tfrac{n_j}{2}) \right] \beta_j \,. \tag{S.10}$$

86 We numerically propagate uncertainty in the positions of the vent and reference feature

87 to estimate uncertainty in pixel dimensions and absolute position. From these calculations

88 for Events 1 and 2 (Observation Site 1), the image center pixel dimensions are $(dx, dz) =$

89 $(3.3 \pm 0.06, 3.5 \pm 0.06)$ m, the camera vertical field of view at the vent distance is 2720 m,

90 and estimated pixel positional errors for features near the center image are $\pm(1, 30)$ m in

91 x and z coordinates, respectively, and increase approximately linearly towards the image

92 edges to a maximum of $\pm(30, 75)$ m. For Event 3 (Observation Site 2), pixel dimensions

93 are $(dx, dz) = (2.7 \pm 0.06, 2.9 \pm 0.06)$ m, the vertical field of view at vent distance is 2270

94 m, and estimated positional errors are similar to those for Events 1 and 2. The analyses

95 presented below rely almost exclusively on pixels from features near image centers with

96 relatively lower uncertainty values, and therefore absolute positional error are generally

97 $\leq \pm(15, 60)$ m for all three events. Note that these error values are estimated for the

98 geometrical projection alone, assuming objects lie in the projection plane (Figure S2),

99 and result primarily from uncertainty in the absolute positions of the reference feature

100 and vent.

September 14, 2023, 7:20pm

1.4. Image re-gridding

Image stretching during the above image projection step results in pixel positions that are not regularly spaced in (x, z) (see Figure S2c,d). The resampling of thermal images and masks into regularly gridded spatiotemporal coordinates is done in two steps. First, individual frames are resampled from projected positions onto regularly sampled grid coordinates (x, z) (Figure S2e). Re-gridding is performed using a linear interpolation in the MATLAB 'scatteredInterpolant' function. Next, because the thermal camera frame rate is slightly variable, we used the MATLAB 'resmaple' function with piecewise cubic Hermite interpolation. This function outputs a MATLAB structure which contains a regularly sampled data cube $\Delta T(x, z, t)$.

2. Two-dimensional (2D) Velocity Field Retrieval Using Optical Flow Analysis

Here we describe the details of obtaining 2D velocity fields using the Optical Flow toolbox of Sun, Roth, and Black (2014). Their code was used unaltered, and we do not include it in the our available code, but driver scripts and additional functions built for the filtering process described below are included. There are two key controls that govern the extent to which we resolve the velocity field with Optical Flow. First, the sampling interval must fully resolve the turnover time of the coherent structure we are tracking (generally $\gtrsim 5$ s). Second, the rise speed of any feature must be similar or greater than the "grid speed" dx/dt set by the image spatial resolution dx and sampling rate dt, such that the classical Courant number is of order 1.

$$C = \overline{||u, v||}\frac{dt}{dx} \gtrsim 1, \qquad (S.11)$$

120 where $\overline{||u,v||}$ is the mean of the velocity field magnitude in the plume. For pixel sizes of

121 about 3 m and frame intervals of 0.1 to 0.2 s, velocities of 15 to 30 m/s are comparable to a

122 displacement of about 1 pixel per frame. Motions significantly faster than this are not fully

123 resolved because displacements are very large between frames, but tracking motions much

124 slower than this introduces unphysical noise to the velocity field estimation, as shown in

125 Figure S3. Therefore the 10 Hz sampling rate of the camera is higher than is required to

126 resolve coherent structures rising at typical speeds of about $\sim$ 5 to 25 m/s or turning over

127 with periods of $\gtrsim$ 10s, and we first downsample the video to every second frame before

128 applying the Optical Flow analysis. The choice of every second frame balances resolving

129 slower plume motions while also minimizing the number of frames for which velocity fields

130 must be interpolated. To eliminate remaining high-frequency noise after obtaining optical

131 flow fields, we then apply a low-pass filter to the velocity fields over the time dimension

132 t, and finally interpolate velocity fields for frames not included in downsampling. The

133 frequency cutoff for low-pass filtering is chosen based on the Courant condition such that

134 it is about half the ratio of dominant plume flow velocities to the pixel grid spacing,

$$f \approx (0.5)\frac{\overline{||u,v||}}{dx}, \tag{S.12}$$

136 This choice of frequency cutoff (about 0.5 to 1 Hz) produces velocity fields that are spa-

137 tially coherent and robustly capture plume motions with minimal noise over the timescales

138 of plume rise or the overturn of large eddies ($\gg$ 1 s). Obtaining optical flow velocities in

139 this manner produces velocities that are accurate compared with manual calculations to

140 within a few percent.

3.   Atmospheric Profile Removal Methods Supplement

Here we present additional details on the atmospheric profile removal steps, including height uncertainty estimation, late-time filtering, and additional checks on the choice of ΔT_{mode}.

3.1. Height uncertainty estimation

We estimate the height uncertainty of pixels in the projected images, so that pixels with large height uncertainty can be filtered out when fitting the atmospheric profile to the data. Figure S4 shows the two main sources of pixel height uncertainty, and the estimate of the two uncertainties for a sample frame of Event 3. For a given column feature, error in the height estimation arises if the feature is farther from or closer to the camera than the assumed projection plane above the vent. Because of the upward camera viewing angle, an object that is farther than the projection plane will likely have an underestimated height for features at the edge of the column, and an object that is closer will likely have an overestimated height. Therefore for a perfectly vertical, conical plume centered above the vent, the 3D shape of the plume (i.e. the plume radius) will generally cause the projected height to overestimate the true height since the outer visible portions of the plume will lie outside the projection plane and relatively closer to the camera. We refer to this height uncertainty as the radial error in z (Figure S4a). Additional (and greater) height uncertainty arises where the plume center axis is not centered above the vent (e.g. due to wind transport), such that the position of features may be ambiguously closer to or farther from the camera than implied by the assumed projection plane. We refer to this uncertainty as the axial uncertainty in z (Figure S4b).

September 14, 2023, 7:20pm

161 For all pixels in all frames as a function of height, we estimate the combined height

162 uncertainty using the geometrical relationships shown in Figure S4, combined with sim-

163 plifying assumptions on column geometry. We use the shape of the plume masks derived

164 from the plumeTracker algorithm (Bombrun et al., 2018, yellow line in Figure S4c) to

165 estimate both radial and axial height uncertainties. First, we use the mask width as a

166 proxy for column diameter. Second, we use distance in x between the mask centerline

167 and the vent as a proxy for the magnitude of uncertainty in distance to the camera. This

168 choice is based on the assumption that plume advection along the visible x coordinate is

169 of similar magnitude to advection into or out of the projection plane. This is broadly true

170 for our three Events based on field observations, in which columns were generally shifted

171 north-northwest by prevailing winds at altitude. Figure S4d shows the resulting estimated

172 maximum combined height uncertainty (generally occurring near the plume centerline)

173 for pixels in the plume mask as a function of altitude z, where the solid blue line gives

174 the estimated height radial error, and the shaded blue region gives the axial uncertainty

175 resulting from the column axial position. In this example, the plume is approximately

176 centered above the vent for $z \lesssim 6800$ m a.s.l., and the estimated height error increases lin-

177 early with both increasing plume radius and elevation angle from the camera, but remains

178 less than about 50 m. Above 6800 m where the plume is bent away from the vent, the

179 uncertainty in height quickly increases in both magnitude and sign, ranging from about

180 -50 to +150 m.

3.2. Late Time Filtering

181 The transient Events 2 and 3 are conducive to atmospheric profile fitting by virtue

182 of rapid decay in source heat flux. At large time after the Event onset, remnants of

September 14, 2023, 7:20pm

the column become increasingly quiescent and approach thermal equilibrium with the background atmosphere. Figure S5 compares ΔT for two frames of Event 3 at $t = 60$ and $t = 245$ s. ΔT is both much lower and much more uniform throughout the column for the late-time frame, and we take advantage of this to apply the atmospheric filtering. Figure S5b shows a heat map of $T_b - T_a$ as a function of time for Event 3, where each column of data is the normalized probability density function (PDF) for pixels in a single frame. Initially, during the peak heat flux from the vent, the PDF of ΔT_i has a mode of about 60 K and wide standard deviation of about 30 K. At late times as column heat flux decays, however, the values converge towards an approximately constant mode of about -12.4 K with a standard deviation of only about 1 K (red box), indicating that the plume is near thermal equilibrium with the atmosphere at this relative temperature difference between image and satellite data. This constant value corresponds to peak of filtered PDFs as shown in Figure 4(g-i) of the main manuscript, from which we estimate $\Delta T_{mode} = -13.6$ K.

3.3. Apparent Minimum Temperatures and Atmospheric Profile Fit Residuals

To add confidence in our estimate of ΔT_{mode} based on filtered PDF half-maxima, here we discuss an additional filtering step. As shown in Figure 4, the action of column rise and turbulent entrainment and mixing causes column temperatures to approach those of atmospheric background approximately asymptotically. At any given height in the column, turbulent entrainment and thermal mixing act to combine two packages of fluid: the relatively hot plume mixture, and the cold and comparatively uniform temperature of the ambient air. As a result, temperature distributions in the data are frequently bi-modal, and the statistical distribution of the coldest temperatures can be used to

find pixels that represent the coldest background temperature being entrained into the column and towards which temperatures are approaching asymptotically. To this end, for all filtered pixel *rows* within the plume (see Figure 4e) we find the minimum value of ΔT. Since the initial masking process should eliminate the majority of partially transparent pixels, we expect that these apparent ΔT minima are statistically representative of the coldest atmosphere being drawn into the plume.

Figure S6(a-c) shows the resulting PDFs of row-wise apparent minima for Events 1-3, respectively, as purple dashed lines. The filtered PDFs of Figure 4(g-i) are shown in blue and orange for comparison. For the Event 3 example in Figure S6c, this procedure gives a population of about 20,000 apparent minima values (about 400 pixel rows within the range of good height estimates over about 50 frames). The apparent minima peaks approximately coincide with the half-maximum value of the initially filtered pixels (vertical dashed grey lines), except in the case of Event 1. Because Event 1 is a steady plume and lacks a well-equilibrated 'late-time' population of pixels, the apparent minima peak is more diffuse. We take the long tails in apparent minima PDFs at colder temperatures as representative of partially transparent pixels incorporating information from cold sky background. That apparent minima peaks for Events 2 and 3 coincide with peak half-maxima of the filtered pixels (orange lines) adds confidence that these values correspond approximately to the atmospheric background temperatures, motivating our choice of ΔT_{mode}. Since this is not the case for Event 1, however, for consistency we skip this additional apparent minima step in our final results, and retain only the half-maxima definition of ΔT_{mode} as described in the main manuscript.

Panels (d), (e), and (f) in Figure S6 show the residual errors in the modal value of $T_b - T_a$ as a function of height for Events 1, 2, and 3, respectively. The blue and orange curves correspond to the mode for all plume pixels and filtered plume pixels, respectively, as in panel (e). As expected for all events, the fit for all pixels is generally poor near the vent where temperatures are high and above about 7500 to 8000 m a.s.l., where plumes becomes increasingly transparent and pixel height estimates are increasingly uncertain. In between these heights for Events 2 and 3, fit of filtered pixels with the atmospheric profile is generally very good. This is in part facilitated by the transient nature of these events, which allows a better fit for thermally well-mixed plumes at late time. For Event 1, which is both steady in time (and thus lacks "late-time" data to use) and increasingly bent by winds with altitude above the vent (see Figure 3a), there is a more narrow height range of about 6700 to 7300 m a.s.l. where the profile fit is good. Below this height the steady plume is not thermally well mixed, and above this height the plume is likely both increasingly transparent and strongly transported out of the projection plane, resulting in large height uncertainty.

3.4. Effects on Power Law Fits of ΔT_{mode} Approximation

The linear approximation using ΔT_{mode} in Equation 6 (main manuscript) is valid so long as the maximum values of ΔT are not more than 100 to 200 K. For example, assuming that the satellite atmospheric profile gives the true temperature (about 267 to 275 K between 6500 and 7500 m a.s.l.), then for the largest estimated magnitude of $\Delta T_{mode} = -12.4$ K (Event 3, Figure S6c), Equation 5 implies a combined emission and transmission loss $(\varepsilon\xi) \approx 0.83$. In this case, the maximum error introduced to our ΔT approximation for the hottest (unsaturated) pixels is about 7 K, and typically less than about 2 K. This

$_{249}$ approach is further aided in our case by the combination of high altitude (observation

$_{250}$ sites about 5200 m a.s.l.), a dry environment, and generally clear-sky background, which

$_{251}$ are well-suited to minimal (though non-zero) transmission loss of thermal emissions at

$_{252}$ our viewing distances (Harris, 2013).

$_{253}$ Figure S7 compares power law fit results using the scalar temperature correction ΔT_{mode}

$_{254}$ (Equation 6) against the results of applying a multiplicative correction to brightness

$_{255}$ temperature data (Equation 5). Panel (a) shows absolute temperatures after applying four

$_{256}$ different multiplicative corrections ($\epsilon\xi$) ranging from 0.6 to 1.0 to brightness temperature

$_{257}$ data. A value of 0.83 gives the best fit with the satellite-derived atmospheric profiles. In

$_{258}$ panel (b), we calculate the excess temperature 95th percentile. For cases besides ($\epsilon\xi$) =

$_{259}$ 0.83, multiplicative corrections must be adjusted by an additive constant to align the

$_{260}$ decay curves for comparison with the scalar-adjusted ΔT employed in the main manuscript

$_{261}$ (black line in panel (b)). In panels (c) and (d), the power law fit results show that resulting

$_{262}$ B estimates are insensitive to the choice of correction, though RMS fit error increases for

$_{263}$ low correction values of ($\epsilon\xi$) = 0.6.

Table S1. Table of variables for supporting information.

Variable	Description	Units
i_{ref}	Vertical image coordinate of reference feature	pixels
j_{ref}	Horizontal image coordinate of reference feature	pixels
n_i	Height of camera field of view	pixels
n_j	Width of camera field of view	pixels
β_i	Vertical angular field of view for a single pixel	radians
β_j	Horizontal angular field of view for a single pixel	radians
ϵ	Emissivity of target plume	-
θ_0	Camera view centerline elevation angle to horizontal	radians
$d\theta_{ref}$	Angular elevation to reference point along camera centerline	radians
ξ	Transmissivity of the atmospheric path between camera and plume	-
ϕ_0	Camera view centerline azimuth	rad
$d\phi_{ref}$	Angular distance: camera centerline to reference azimuth	rad

Notation:

Figure S8. Tracking and curve-fitting results for Event 1, tracks 1-4. Left-most column shows tracked feature outlines at various time steps in blue, and the total outline (enclosing all tracked pixels for all times) in orange. The gray outline shows the time-averaged image mask as shown in Figure 7 of the main manuscript. The second column from the left shows the tracked feature effective radius (taken as the square root of total pixel area) versus height (of pixel values at each time step) above the vent. The linear model 95% confidence bounds for $R(z)$ are shown with blue dashed lines. The third column from the left shows evolution with height of the reconstructed excess temperature distribution. Light gray and dark gray fields show the 5-95 and 25-75 percentile range, respectively, and the dark gray line gives the mean. The curve-fitted ΔT_{95} is highlighted with blue dots, and the fit confidence 95% bounds are again shown with blue dashed lines. Note that the plotted power law fit confidence bounds shown are for the central z_0 estimate only, but the printed uncertainty in B includes for the range of uncertainty in z_0. We also report the manually identified quality check (QC) value, where 0 = poor, 1 = ok, 2 = excellent (see text for description). The second-from-right and right-most columns show, respectively, the percentage of pixels at each height that are removed from curve-fitting due to either temperature saturation or large height error. Saturated and height-filtered pixels are removed from the temperature fit, while only height-filtered pixels are removed from the radius fit.
