17 **Key Points:**

- 18 • SYM-H growth under northward IMF conditions and highly stretched magneto-
19 tail.
20 • The central plasma sheet was highly dense during the plateau phase of SYM-H.
21 • Models need to account for the state of the Magnetosphere to successfully repro-
22 duce all the features of the SYM-H index.

23 **Abstract**

24 The total energy transfer from the solar wind to the magnetosphere is governed by the
 25 reconnection rate at the magnetosphere edges as the IMF B_z turns southward. The de-
 26 layed response of the ring current to solar wind driving can account for the anomalous
 27 growth of the SYM-H under northward IMF B_z . The geomagnetic storm on 21-22 Jan-
 28 uary 2005 is considered to be anomalous as the SYM-H index that signifies the strength
 29 of ring current, grows and has a sustained peak value lasting more than 6 hrs under north-
 30 ward IMF B_z conditions. In this work, first the standard WINDMI model is utilized to
 31 estimate the growth and decay of various magnetospheric currents by using several so-
 32 lar wind-magnetopshre coupling functions. However, it is found that the WINDMI model
 33 driven by any of these coupling functions is not fully able to explain the enhancement
 34 of SYM-H under northward IMF B_z . The SYM-H variations during the entire duration
 35 of the storm were only reproduced when the effects of the dense plasma sheet were in-
 36 cluded in the WINDMI model. The limitations of directly-driven models relying purely
 37 on the solar wind parameters and not accounting for the state of the magnetosphere are
 38 highlighted by this work.

39 **Plain Language Summary**

40 The energy transfer from the solar wind to the Earth's magnetosphere is most ef-
 41 ficient under southward IMF B_z conditions. Generally, the southward IMF B_z drives the
 42 ring current which is measured by the Dst/SYM-H index. The storm on 21 January 2005
 43 is one of the rarest events which developed under northward IMF B_z conditions. The
 44 geomagnetic disturbances due to the storm, that is signified by the SYM-H index at low
 45 latitudes, continued to grow for more than six hours, reaching a minimum value of -101
 46 nT after northward turning of the IMF B_z . In this work, we have tried to estimate the
 47 SYM-H by using various solar wind-magnetosphere coupling functions as input to the
 48 MINDMI model. However, none of these coupling functions could predict this unusual
 49 growth of SYM-H index under the northward IMF B_z conditions. A highly dense plasma
 50 sheet was observed during the anomalous period and incorporating this in the WINDMI
 51 model led to the successful reproduction of the observed magnetic disturbance. This in-
 52 vestigation clearly shows the important role of the state of the magnetosphere in ener-
 53 gizing the magnetospheric currents. Therefore, it is suggested that the space weather mod-
 54 els need to include both the conditions of solar wind and magnetosphere in order to get
 55 a better prediction of the strength of the ring current.

56 **1 Introduction**

57 The energy and mass transfer from the solar wind to the Magnetosphere-Ionosphere(MI)
 58 system depends on solar wind parameters and the state of the magnetosphere and iono-
 59 sphere. A great many theories have been proposed to quantify these interactions (Borovsky,
 60 2013; Newell et al., 2007; Gonzalez, 1990) most of which are based on the classical Dungey
 61 paradigm (Dungey, 1961). The largest energy reservoirs in the magnetosphere are the
 62 westward flowing ring current and the magnetotail current. The ring current gets ener-
 63 gized during a geomagnetic storm when the z-component of Interplanetary magnetic field
 64 (IMF B_z) turns southward. The energy transfer from the solar wind is more effective
 65 when conditions suitable for magnetic reconnection are present on the dayside magne-
 66 topause (Borovsky & Birn, 2014). The orientation of the IMF heavily controls the rate
 67 and location of reconnection. While the most effective reconnection happens under south-
 68 ward IMF B_z conditions, other solar wind parameters significantly affect it (Newell et
 69 al., 2007).

70 Magnetospheric dynamics are quite distinct when the IMF B_z is northward. The
 71 geoeffectiveness of the solar wind drops significantly under northward IMF conditions.
 72 Reconnection takes place at high latitudes leading to a four-cell convection pattern (Burke

et al., 1979). Parameters like the solar wind, IMF B_y , geomagnetic dipole field, and the dipole tilt control the energy and mass transfer during northward IMF (Li et al., 2008; Reistad et al., 2019). Under extended periods of northward IMF B_z conditions the plasma sheet transforms into a cold dense plasma sheet (CDPS) (Sorathia et al., 2019; Taylor et al., 2008). Reconnection occurs at locations poleward of the cusp that lead to the capture of interplanetary flux tubes that sometimes contain filament material by the magnetosphere to create the CDPS (Kozyra et al., 2013; Li et al., 2008; Palmroth et al., 2006). This preconditioning which typically takes about 3 hrs is known to lead to a stronger geomagnetic storm if the IMF B_z turns southward immediately after the period of northward IMF B_z (Wing et al., 2006). The development and recovery of most of the geomagnetic storms in recorded history can be explained by one or more of these simplified theories but there have also been a few reported events that were deemed “anomalous” since the storm was reported to have developed when no energy was being transferred from the solar wind, typically associated with a period of northward IMF B_z (Du et al., 2008; Simi et al., 2012; Kleimenova et al., 2015).

The storm on 21 January 2005 is the only reported event that had a main phase and extended peak lasting more than 6 hrs under northward IMF B_z condition. A few researchers have analyzed the cause of this anomalous storm and modeled it using physics-based and empirical models (Du et al., 2008; Kozyra et al., 2014; Dmitriev et al., 2014; Kalegaev et al., 2015). Storage and delayed injection were provided as a plausible explanation for the enhanced SYM-H during the northward IMF period by Du et al. (2008) and Kane (2012). Others have discussed the unaccounted contributions from additional solar wind parameters, magnetospheric and ionospheric currents (Troshichev & Janzhura, 2012; Dmitriev et al., 2014). The presence of a cold dense plasma sheet that enabled the extreme compression to energize particles adiabatically has also been suggested as a possible energization mechanism (Kozyra et al., 2013). However, none of these theories could properly explain the growth of the ring current under the northward IMF B_z condition. Therefore, the fundamental question that needs to be answered is what drives the ring current during northward IMF B_z conditions when there is no direct energy input from the solar wind. In this study, we successfully reproduce all the features of the 21 January 2005 storm by using the WINDMI model (Horton & Doxas, 1998; Spencer et al., 2007; Patra et al., 2011) driven by a few standard coupling functions to interpret the global magnetosphere-ionosphere system response. The result reveals the strength of the ring current is not only controlled by the solar wind conditions but also depends on the state of magnetosphere.

2 Event Overview

The coronal mass ejection that erupted on 20 January 2005 from the X7.1/3B solar flare in the northwestern quadrant of the solar disk (14°N , 61°W), caused a moderate geomagnetic storm on 21 January 2005 (Foullon et al., 2007). Figure 1 shows the solar wind parameters at the L1 point (in geocentric solar magnetospheric coordinate system) as measured by the Advance Composition Explorer (ACE) satellite. These have been shifted by 24 mins to align with the geomagnetic signatures of the first storm sudden commencement (SSC). The strength of the geomagnetic storm during 21-22 January 2005 as signified by the geomagnetic indices is shown in the figure along with the magnetopause standoff distance (L_{mp} in R_E). This storm is mainly characterized by two storm sudden commencements (indicated as SSC-1 and SSC-2 in red dashed lines) associated with two consecutive interplanetary shocks. The ACE satellite detected a large coronal mass ejection at \sim 16:48 UT that arrived at the magnetopause at \sim 17:12 UT on 21 January triggering SSC-1 and \sim 1.5 hours later (at 18:43 UT) another CME shock front arrived that triggered SSC-2. It can be seen that the solar wind parameters ($|B|$, solar wind density, and velocity) changed sharply at these times. The proton density N increased from 2 cc^{-1} to 22 cc^{-1} during SSC-1 and further increased to an unusually high value

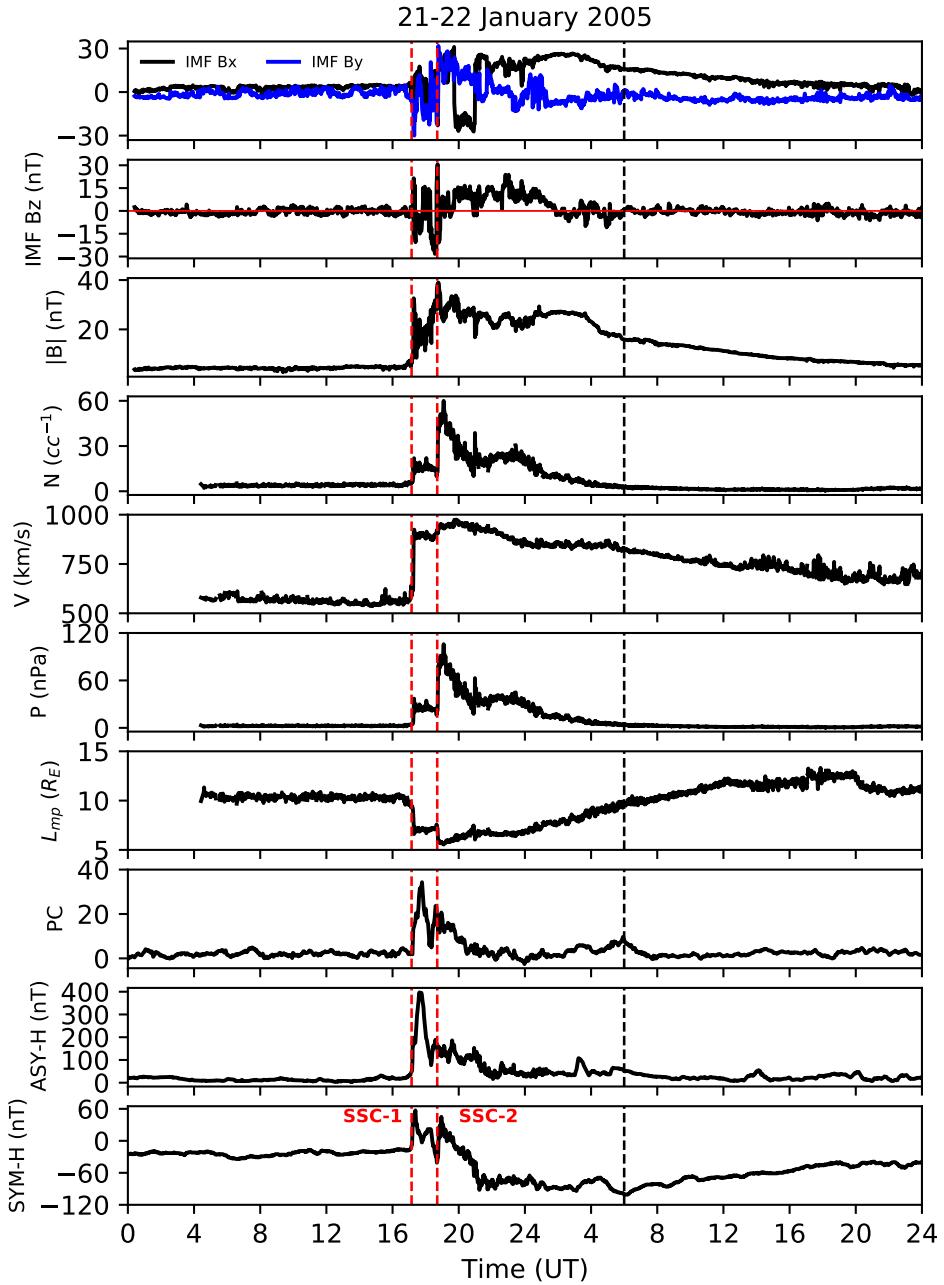

Figure 1. From top to bottom are X and Y components of IMF ($IMF\ B_x$ and $IMF\ B_y$) in blue and black lines, north-south or Z component of IMF ($IMF\ B_z$ in nT), total magnetic field intensity ($|B|$ in nT), solar wind proton density (N in cc^{-1}), solar wind velocity (V in km/s), solar wind dynamic pressure (P in nPa), variation of the magnetopause standoff distance (L_{mp} in R_E), polar cap index (PC), ASY-H index in nT, and geomagnetic storm index (SYM-H in nT). The red dashed vertical are drawn to identify the SSCs.

of $62\text{ }cc^{-1}$. The solar wind velocity increased from 565 km/s to 900 km/s. The solar wind dynamic pressure ($P = \frac{1}{2}\rho V^2$) increased from 2 nPa to 35 nPa during the SSC-1 and then it increased to the significantly high value of 106 nPa during SSC-2. Due to the high dynamic pressure, the magnetopause standoff distance was estimated to be significantly reduced from $\sim 10.3\text{ }R_E$ to $5.3\text{ }R_E$ based on the formula provided in Kivelson and Russell (1995). The subsolar magnetopause was continuously located inside geosynchronous orbit ($\sim 6R_E$) due to the strong compression during initial and main phases of the storm. It is for the first time that the upstream solar wind was observed at geosynchronous orbit for almost 2 hr due to the extreme compression caused by the solar wind dynamic pressure (Dmitriev et al., 2014).

In response to SSC-1, the SYM-H increased from -17 nT to 55 nT. Approximately 1.5 hours later (at 18:43 UT) the second shock front arrived causing the SSC-2 that led to a second increase in the SYM-H value. It is around this time that the IMF B_z turned northward, but surprisingly the storm's main phase continued to develop. In between, the IMF B_z turned southward within minutes of the arrival of the SSC-1 at 17:20 UT, it briefly turned northward at 17:47 UT but turned southward again at 18:18 UT, and remained southward until a few minutes before the arrival of the SSC-2 at 18:45 UT. The SYM-H reached its lowest value of -101 nT at 06:00 UT on 22 January. The IMF B_z was continuously northward from 19:40 UT, 21 January to 02:45 UT, 22 January 2005. Typically, when the IMF B_z turns northward the ring current starts to recover and this recovery is observed in the SYM-H values. But surprisingly during the period from 19:40 UT, 21 January - 02:45 UT, 22 January 2005, the SYM-H index grew to a value of around -90 nT by 21:30 UT and remained elevated afterwards which is referred to as the "plateau" region. This is highly unusual and termed as "anomalous" as reported by a few other studies (Du et al., 2008; McKenna-Lawlor et al., 2010; Kozyra et al., 2013, 2014; Bag et al., 2023). Additionally, the polar cap index (PC), and the indicator of ring current asymmetry (ASY-H) were significantly high during the initial phase but dropped quickly during the main phase.

3 Results and Discussion

In order to explain this unusual growth of the ring current, the low order physics-based model of the magnetosphere-ionosphere system, WINDMI (Horton & Doxas, 1998; Spencer et al., 2007) is used. The WINDMI model is derived from the fluid plasma equations that give a system of eight ordinary differential equations driven by a potential derived from solar wind coupling functions. The eight equations of the model are given by:

$$L \frac{dI}{dt} = V_{sw}(t) - V + M \frac{dI_1}{dt} \quad (1)$$

$$C \frac{dV}{dt} = I - I_1 - I_{ps} - \Sigma V \quad (2)$$

$$\frac{3}{2} \frac{dp}{dt} = \frac{\Sigma V^2}{\Omega_{cps}} - u_0 p K_{\parallel}^{1/2} \Theta(u) - \frac{p V A_{eff}}{\Omega_{cps} B_{tr} L_y} - \frac{3p}{2\tau_E} \quad (3)$$

$$\frac{dK_{\parallel}}{dt} = I_{ps} V - \frac{K_{\parallel}}{\tau_{\parallel}} \quad (4)$$

$$L_I \frac{dI_1}{dt} = V - V_I + M \frac{dI}{dt} \quad (5)$$

$$C_I \frac{dV_I}{dt} = I_1 - I_2 - \Sigma_I V_I \quad (6)$$

$$L_2 \frac{dI_2}{dt} = V_I - (R_{prc} + R_{A2}) I_2 \quad (7)$$

$$\frac{dW_{rc}}{dt} = R_{prc} I_2^2 + \frac{p V A_{eff}}{B_{tr} L_y} - \frac{W_{rc}}{\tau_{rc}} \quad (8)$$

The model is driven by a potential field that is a function of the solar wind parameters (V_{sw}). The nonlinear equations of the model trace the flow of electromagnetic and mechanical energy through eight pairs of transfer terms. The remaining terms describe the loss of energy from the magnetosphere-ionosphere system through plasma injection, ionospheric losses and ring current energy losses. The coefficients in the differential equations are physical parameters of the magnetosphere-ionosphere system. The quantities L, C, Σ, L_1, C_I and Σ_I are the magnetospheric and ionospheric inductances, capacitances, and conductances respectively. A_{eff} is an effective aperture for particle injection into the ring current. The resistances in the partial ring current and region-2 current, I_2 are R_{prc} and R_{A2} respectively, and L_2 is the inductance of the region-2 current. The coefficient u_0 in eqn. 3 is a heat flux limiting parameter. The energy confinement times for the central plasma sheet, parallel kinetic energy and ring current energy are τ_E, τ_k and τ_{rc} respectively. The effective width of the magnetosphere is L_y and the transition region magnetic field is given by B_{tr} . The pressure gradient driven current is given by $I_{ps} = L_x(p/\mu_0)^{1/2}$, where L_x is the effective length of the magnetotail. The outputs of the model relevant to the current study are the magnetotail current (I), ring current energy (W_{rc}), in addition to all the magnetospheric field aligned currents.

The solar wind-magnetosphere interaction is usually quantified by coupling functions. The earliest of these models was the half-wave rectified motional electric field which proposed that the x-component of solar wind velocity (v_x) and the southward component of IMF $B_z(B_s)$ were the most important parameters (Burton et al., 1975). Additional coupling functions have been introduced that account for the effect of dynamic pressure (P), the perpendicular component of the magnetic field (B_T), and the clock angle ($\theta = \tan^{-1}(B_y/B_z)$), magnetic flux at the magnetopause (Φ_{mp}), magnetosonic mach number, plasma beta value, mass density of the solar wind upstream of the bow shock (ρ_o), and thermal pressure (P_{th}) (Siscoe et al., 2002; Newell et al., 2007; Borovsky, 2008). These coupling functions are combined with the effective thickness of the magnetosphere L_y^{eff} to obtain the driving potential ($V_{sw} = V_{xxx}$) for the model. We have chosen five coupling functions for this study as defined below:

$$V_{rectified} = v_x B_s^{IMF} L_y^{eff} \quad — Rectified \quad (9)$$

$$V_{siscoe} = 40.0(kV) + 57.6v_x B_T \sin^2(\theta/2) P^{-1/6} \quad — Siscoe \quad (10)$$

$$V_{newell} = \frac{d\Phi_{mp}}{dt} = v_x^{4/3} B_T^{2/3} \sin^{8/3}(\theta/2) \quad — Newell \quad (11)$$

$$V_{newell-P} = P^{1/2} \frac{d\Phi_{mp}}{dt} \quad — Newell-P \quad (12)$$

$$V_{borovsky} = f(v, B, P, \theta, \rho_o, P_{th}) \quad — Borovsky \quad (13)$$

For the detailed information of the coupling functions and their performance please refer to Spencer et al. (2011). The chosen coupling functions are normalized based on the method proposed by Spencer et al. (2011), so that only the qualitative differences introduced by each function are highlighted. The WINDMI model estimates the state of the magnetosphere-ionosphere system by optimizing the physical model parameters using a genetic algorithm (Patra et al., 2011). The contribution of the symmetric ring current energy (W_{rc}) to the SYM-H index is calculated using the Dessler-Parker-Sckopke relationship (Dessler & Parker, 1959; Sckopke, 1966) that relates the energy in the ring current with the magnetic perturbations at low latitudes on the surface of earth. The magnetic perturbation at low latitudes due to the magnetopause currents is estimated as $7.26\sqrt{P}$ based on the empirical relationship given by Burton et al. (1975). The contribution of the tail current (I) to the SYM-H index is estimated from the tail current magnitude calculated by the WINDMI model in eqn. 1 multiplied by a geometric factor (Patra et al., 2011). The sum of all three current contributions gives the estimated

202 SYM-H value calculated by the WINDMI model for each of the coupling functions as
 203 shown in fig 2.

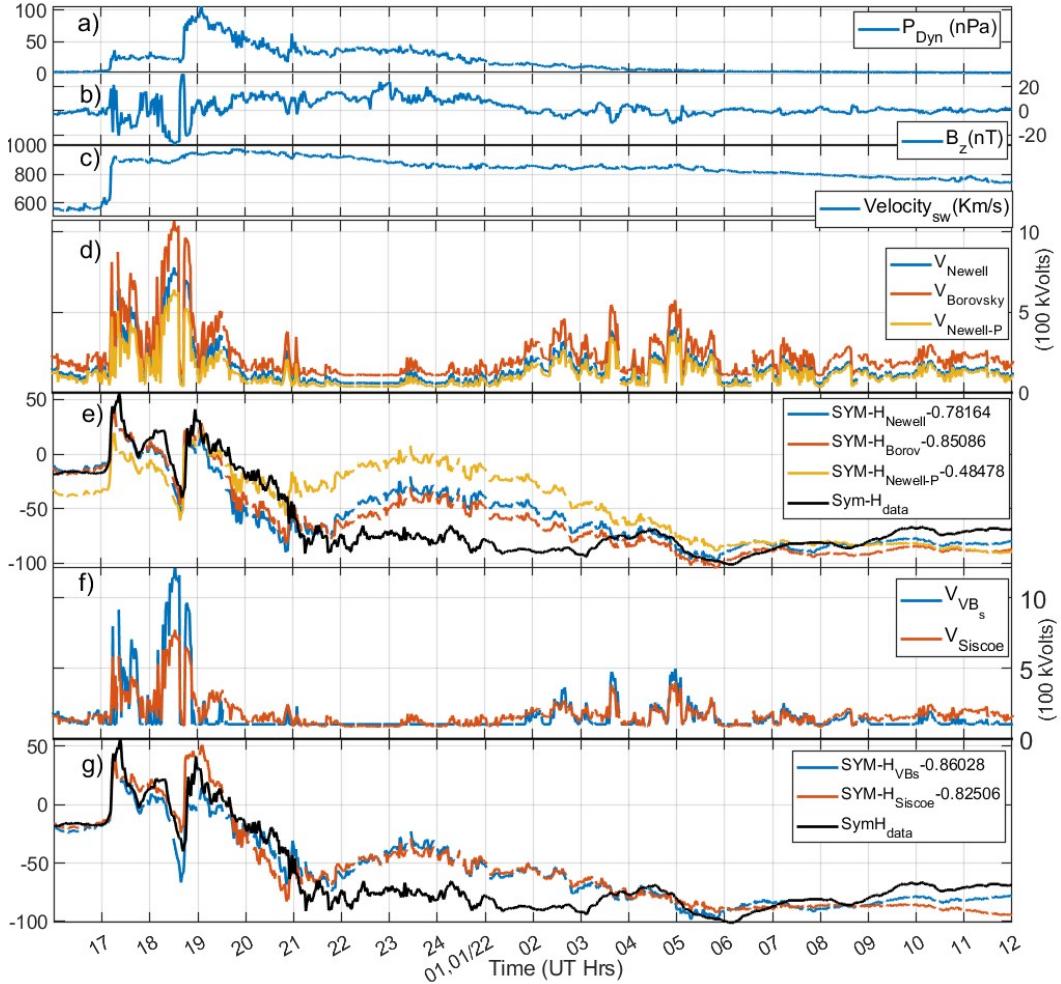

Figure 2. Top three panels (a-c) show the shifted solar wind dynamic pressure, z-component of magnetic field, and velocity measured at ACE. The coupling functions (d,f), the modeled and measured SYM-H values (e,g) along with their correlation coefficients for the 21 January 2005 storm are shown in the bottom four panels.

204 The best fit results along with the normalized coupling function values are shown
 205 in fig. 2 (d-g). During the initial and main phase of the storm until around 21:30 UT,
 206 almost all the coupling functions are able to provide acceptable fits. The rectified E-field
 207 and Borovsky's coupling functions provide the best fits with correlation values of 0.86
 208 and 0.85 respectively as shown in the panels showing the modeled SYM-H values in fig.
 209 2. The initial growth of the SYM-H after the northward turning of IMF B_z can be cor-
 210 rectly estimated due to the reduction in magnetopause currents and the system delay
 211 accounted for by the model. From 21:30 UT onwards until 04 UT in the plateau phase
 212 the model tends to underpredict the SYM-H values.

213 The consistent underestimation by the WINDMI model from 21:30 - 04:00 UT is
 214 due to the fact that none of the coupling functions predict any substantial energy injec-
 215 tion in this period. This suggests that directly driven mechanisms even after account-

ing for other solar wind variables as suggested by Kuznetsova and Laptukhov (2011), and Troshichev and Janzhura (2012), might not have been the dominant contributor to the ring current during this phase. A simple delayed rise of the ring current that can be from 0-8 hrs and slow decay was suggested as a likely cause by Kane (2012), and Gonzalez and Echer (2005). The WINDMI model successfully reproduced the delayed rise in SYM-H, and predicts a slow decay with a relatively high ring current time constant of ~ 40 hrs. The inability of the model to fit the plateau suggests either additional ring current energization mechanisms might have been present or other current sources contributed to the steady SYM-H.

Du et al. (2008) reported that the magnetic field stretching angle was close to zero during the initial phase which signifies a highly distorted magnetosphere and an earthward location of the tail current that suggests a significant contribution from the tail current to the low latitude magnetic disturbance. Empirical and MHD models validated using in-situ and energetic neutral atoms observations have been used to model the various currents' contributions to SYM-H (McKenna-Lawlor et al., 2010; Dmitriev et al., 2014; Kozyra et al., 2014). From these studies, it was inferred that the currents like the field-aligned currents, tail currents, and partial ring current were the dominant contributors during the main and early recovery phase of the storm while the symmetric ring current became dominant after 00:45 UT on 22 January .

Kozyra et al. (2014) reported observations of an intensified auroral oval, isotropic boundary (b2i) at lower latitudes, and the ring current precipitation zones that are evidence for the magnetotail stretching by field line curvature scattering. Kozyra et al. (2013) claim that the 21 January 2005 event was the first and only instance where a strong stretching was observed due to the formation of a dense plasma sheet derived from dense solar filament material. Based on the evidence, it is reasonable to assume that the tail current remained elevated and contributed to the SYM-H index during the main phase. The plasma sheet capacitance parameter C in the WINDMI model eqn. 2 is a function of the plasma sheet density. The capacitance value can be determined using the following expression (Spencer, 2006):

$$C \approx \frac{\pi \rho_m L_x L_z}{B_{x0} B_z L_y} \quad (14)$$

where ρ_m is the plasma sheet density, L_x and L_y are the length and width of the geotail while L_z is the half-width of the plasma sheet. B_{x0} is the magnetic field at $x = 0$ and B_z is constant.

Figure 3(a) shows the plasma sheet density as measured by the Los Alamos National Laboratory Magnetospheric Plasma Analyzers (LANL-MPA). Observations from all the satellites (LANL-95, LANL-84, LANL-97A, LANL-01A, and LANL-02A) during 20:00 - 04:00 magnetic local time (MLT) window are plotted at a given UT. The density increases by almost 6-10 times after the second impulse SSC-2. To reflect this abrupt increase in density we chose a step profile for the plasma sheet capacitance changing from $\sim 70,000F - 560,000F$. The contribution of the various currents to the SYM-H index(SYM-H_{windmi}) as estimated by the WINDMI model driven by the rectified function and density-dependent Capacitance is shown in fig. 3. The model estimates a slow ring current (SYM-H_{rc}) decay with a time constant of ~ 13 hrs. The fast dynamics in the initial and main phases are the result of the Chapman-Ferrao (magnetopause) currents (D_{mp}) and the tail current (SYM-H_{tail}). In the plateau phase the slowly decaying ring current, the still elevated tail current, and the magnetopause current combine to create a near-constant magnetic disturbance that matches with the observed records of the SYM-H index (SYM-H_{data}).

This breakdown of the current contributions to SYM-H also highlights the fallacies in using commonly used terminologies like initial, main, and recovery phases of the

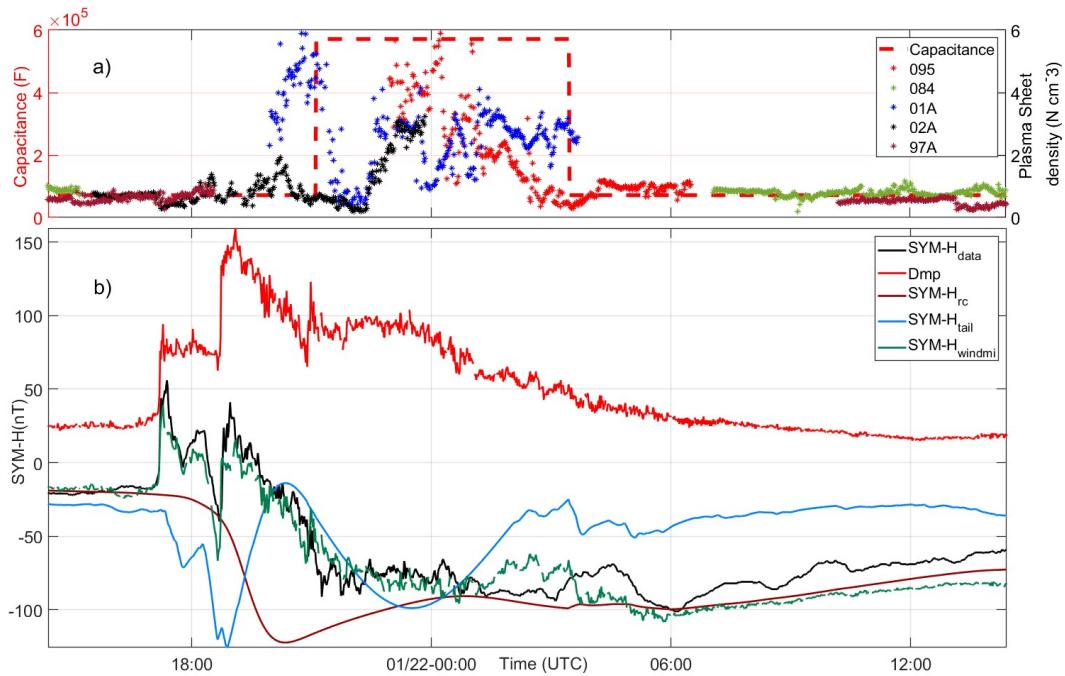

Figure 3. (a) Variation of plasma sheet density measured by different LANL satellites along with the modified plasma sheet capacitance used in the WINDMI model. (b) The best fit currents for the 21 January 2005 storm as estimated by the plasma sheet dependent WINDMI model (see text for details) driven by the rectified VBs input. The magnetopause current (Dmp) is estimated empirically.

265 storm based on just the SYM-H index. It is clear that the storm's main phase starts much
 266 earlier coinciding with the period of negative IMF B_z . The apparent growth of the main
 267 phase and the inflection point in SYM-H at 21:15 UT is in fact due to the recovery of
 268 the CF-current after the SSC-2 at 19:20 UT. The magnetic perturbation caused by the
 269 magnetopause current (D_{mp}) peaked at SSC-2 reaching a value of 55nT and quickly fell
 270 down to a value averaging around 80 nT from 21:15 UT till 24 UT. Hence one should
 271 be careful in interpreting and trying to model the ring current based purely on the ba-
 272 sis of SYM-H.

273 The occurrence of dense plasma sheet and its role in magnetotail dynamics and ring
 274 current intensity was discussed in detail by Borovsky et al. (1997). They suggested three
 275 main sources for the higher density: the outer plasmasphere, high density solar wind,
 276 and ionospheric outflow. A cold dense plasma sheet usually forms under extended pe-
 277 riods of northward IMF B_z (Borovsky & Denton, 2010; Denton & Borovsky, 2012). This
 278 dense material can be injected to the inner magnetosphere either by sudden southward
 279 IMF or a very strong compression (Thomsen et al., 2003). The long lifetime of the ring
 280 current was probably due to particle injection into the inner magnetosphere where the
 281 drift times are longer (Dmitriev et al., 2014). The formation of a warm and later cold
 282 dense plasma sheet within 1 Hr after impact of the second pressure pulse and under north-
 283 ward IMF conditions was reported by Kozyra et al. (2013) during the 21-22 January 2005
 284 storm. They claim that the high densities were driven by the dense solar filament ma-
 285 terial that produced strong diamagnetic stretching despite low levels of magnetic activ-
 286 ity. Du et al. (2008) suggested that energy was initially stored in the tail due to a pre-
 287 vious southward IMF B_z period albeit small and then later injected into the ring cur-
 288 rent leading to the growth of SYM-H. Although no clear physical mechanism for this was
 289 provided, the creation of a dense plasma sheet followed by compression-led injection and
 290 substorms could possibly provide the additional source needed.

291 Fig.4 (left panel) shows the variations of (a) IMF B_z , (b) solar wind pressure (P),
 292 electron flux measured at geosynchronous orbit by (c) LANL-1990-095, (d) LANL-01A,
 293 (e) LANL-02A satellites and proton flux measured by (f) LANL-01A, (g) LANL-02A satel-
 294 lites (h) the westward auroral electrojet (AL index) during 15:00 UT, 21 Jan-06:00 UT,
 295 22 January. The dashed lines are marked to show the time when dispersionless-like in-
 296 jection of energetic particles at geosynchronous orbit are observed. These satellites were
 297 on the night side when the particle enhancements were observed. There are six dispersionless-
 298 like injection observed during this event which are also correlated with AL enhancement.
 299 It is important to note that three (2nd, 3rd, and 4th) dispersionless-like injection are ob-
 300 served under predominantly northward IMF B_z conditions although the fluxes are rel-
 301 atively low to the quiet time level. It can be seen that the solar wind pressure is high
 302 but not changing much during this time. The high solar wind pressure leads to a com-
 303 pressed magnetosphere that can lead to higher losses as the drifting particles might en-
 304 counter the magnetopause and drift out. Alternatively, the possibility of the LANL satel-
 305 lites to be on higher L-shells can not be ruled out since the magnetosphere is highly stretched.
 306 That can also result in lower flux measurements. These substorm-like signatures could
 307 then be just signatures of relaxation of the magnetosphere (Kozyra et al., 2013). The
 308 presence of a stretched magnetotail sustained by a high tail current and dense plasma
 309 sheet during the plateau phase of the storm possibly led to the anomalous SYM-H ob-
 310 servations. The counterbalancing contributions from ring current, tail current, magne-
 311 topause current and the current wedge formed along with the long lifetimes of the ring
 312 current particles during the northward IMF B_z periods might have created conditions
 313 for the plateau observed in the SYM-H index (Ohtani et al., 2001; Lopez et al., 2015).

314 4 Summary

315 To summarize, in the present investigation, a moderate geomagnetic storm with
 316 peak SYM-H value of -110 nT that occurred on 21 January 2005 was unusually found

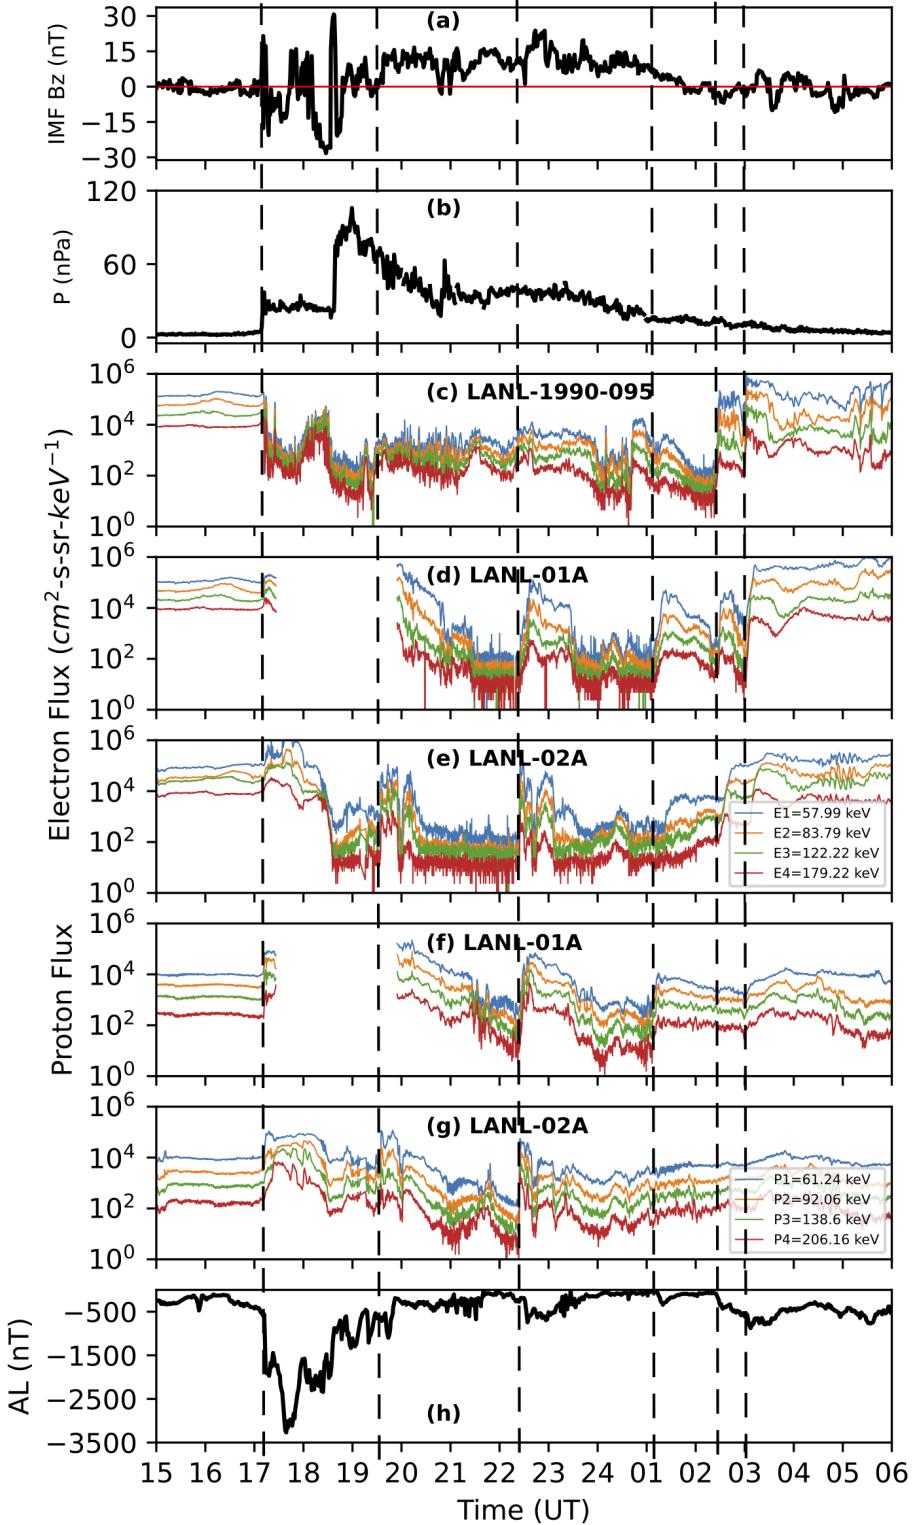

Figure 4. Variations in (a) IMF B_z , (b) Solar wind pressure, electron flux measured at geosynchronous orbit by (c) LANL-1990-095, (d) LANL-01A, (e) LANL-02A satellites, and proton flux measured by (f) LANL-01A, (g) LANL-02A satellites (h) westward auroral electrojet (AL index). The black dashed lines are marked to show the time when the dispersionless-like injections are observed.

317 to develop under northward IMF B_z conditions. The WINDMI model was used to un-
 318 derstand the energization process of the ring current and other currents in the magnetosphere-
 319 ionosphere system by considering various coupling functions as input. It is found that
 320 the WINDMI fits that used the coupling function of Borovsky and rectified motional elec-
 321 tric field as input gave the best correlations with the observed SYM-H. However, it is
 322 to be noted that none of the coupling functions could drive currents in the WINDMI model
 323 to reproduce the exact variation of SYM-H in the plateau phase. A highly dense plasma
 324 sheet was present during the plateau phase of the storm. This coincided with a highly
 325 stretched magnetosphere that suggests a sustained high tail current. Multiple "substorm"
 326 like signatures were found to be present during the northward IMF B_z conditions in the
 327 main phase of the storm that caused magnetic perturbations globally.

328 The WINDMI model was enhanced to include the contribution of plasma sheet den-
 329 sity that allowed the WINDMI model to successfully reproduce all the features of the
 330 storm. The model estimates a slowly decaying ring current and a sustained tail current
 331 in the plateau phase. The long lifetime of the ring current was probably due to parti-
 332 cle injection into the inner magnetosphere where the drift times are longer. A combina-
 333 tion of the highly dense plasma sheet, deep injection of the ring current particles, and
 334 the elevated levels of the magnetopause currents likely caused the apparent growth, plateau
 335 and extremely long recovery of the SYM-H index. The energy transfer from the solar
 336 wind to the magnetosphere-ionosphere system is the key to comprehending and predict-
 337 ing space weather. This study highlights the importance of correctly accounting for the
 338 state of the magnetosphere in successfully modeling currents during a geomagnetic storm.

339 5 Open Research-Data availability statement

340 Data used in this study is made available at [https://zenodo.org/record/7351730#](https://zenodo.org/record/7351730#.Y38w7oLMIoJ)
 341 .Y38w7oLMIoJ. The geomagnetic indices (SYM-H and AL) and solar wind data are ob-
 342 tained from the GSFC/SPDF OMNIWeb (<https://omniweb.gsfc.nasa.gov>). The WINDMI
 343 model v.1 can be run for free at the Community coordinated modeling center (CCMC)
 344 (<https://ccmc.gsfc.nasa.gov/models/WINDMI~1.0>).

345 Acknowledgments
