**Key Points:**

- An anthropogenic dust emission parameterization is developed and implemented in a global climate model.
- Our parameterization predicts that 13.3% of the total dust emission in present day is anthropogenic dust emission.
- Total dust emission increases by 13% from pre-industrial to present day, which results in a dust direct radiative forcing of  $-0.041 \text{ W m}^{-2}$ .

**Key words:**

Anthropogenic dust emission, dust radiative forcing

26 **Abstract**

27 Dust emissions related to anthropogenic activities (i.e., anthropogenic dust (AD)) is not  
28 represented in most global climate models and its radiative impact remains unassessed.  
29 In this study, we develop a new and physically based method to parameterize AD  
30 emission based on the DOE's Energy Exascale Earth System Model version 1 (E3SMv1).  
31 This method relates AD emission to the crop land use fraction in the E3SMv1 land  
32 component. Major AD sources simulated by our parameterization include those over  
33 Central America, the Sahel, North India, and North China. The annual averaged AD  
34 emission is  $567 \text{ Tg yr}^{-1}$  in present-day (year 2000), which contributes to 13.3 % of total  
35 dust emission. Model evaluation against satellite and ground-based observations shows  
36 that the new parameterization can represent AD emissions and global dust cycle  
37 reasonably well. We find that the total dust emission increases by 13 % ( $495 \text{ Tg yr}^{-1}$ )  
38 from 1850 to 2000 mainly due to the cropland land use fraction changes, which induces  
39 a net dust direct effective radiative forcing of  $-0.041 \text{ W m}^{-2}$  at top of the atmosphere.  
40 This AD-induced cooling exceeds 10% of the total anthropogenic aerosol direct effective  
41 radiative forcing from 1750 to 2014 estimated by the Intergovernmental Panel on  
42 Climate Change Sixth Assessment Report. Our findings indicate an important role of AD  
43 in the regional and global climate changes, which should be included in future climate  
44 change assessments.

## 45 **Plain Language Summary**

46 Dust aerosols are generally recognized as natural aerosols whose atmospheric burden  
47 remains stable with time. However, studies have found that anthropogenic activities can  
48 also induce dust emissions. Anthropogenic dust (AD) emission is not represented in  
49 most global climate models, and its impact on climate is not well understood. In this  
50 study, we implement an AD emission parameterization in a global climate model that  
51 physically relates AD emission to cropland fraction. Our modelling results show that  
52 13.3% global dust emission in the present day is from AD sources, which includes those  
53 over Central America, the Sahel, North India, and North China. Due to agricultural  
54 expansion, total dust emission increases by 13% from pre-industrial to present day,  
55 which is dominated by the increase in AD emission. This historical increase results in  
56 cooling effect of dust on climate through scattering and absorbing radiation, which  
57 exceeds 10% of the estimate by the Intergovernmental Panel on Climate Change Sixth  
58 Assessment Report. Our findings indicate an important role of AD in the global climate  
59 changes, which should be included in future climate change assessments.

60

61

## 62 **1 Introduction**

63 Dust aerosols are a key component of the Earth's system, which contribute to  
64 more than half of the total aerosol mass in the atmosphere (Kinne et al., 2006; Textor et  
65 al., 2006). They affect global climate directly by absorbing and scattering solar and  
66 terrestrial radiation and indirectly by serving as cloud condensation nuclei (CCN) and  
67 ice nucleating particles (INPs) to alter the cloud properties. They also have an impact on  
68 the surface concentration of particular matters, which consequently influences the air  
69 quality and human health (Chen et al., 2004). Additionally, dust aerosols play an  
70 important role in the biogeochemical cycle in that the contained metallic elements  
71 provide nutrients to ocean through deposition (Martin, 1990).

72 Dust is generally recognized as natural aerosol that is induced by wind erosion  
73 from arid and semi-arid regions – the global dust burden in the atmosphere is presumed  
74 to be stable with time. As a result, the Intergovernmental Panel on Climate Change  
75 (IPCC) Sixth Assessment Report (AR6) (Forster et al., 2021) does not account for dust  
76 when quantifying anthropogenic aerosol effective radiative forcing from pre-industrial  
77 (PI) to present day (PD). However, a recent work by Kok et al. (2023) reported a 55%  $\pm$   
78 30% increase of atmospheric dust burden from PI to PD using a reconstruction dataset  
79 built upon dust historical deposition records, while the Coupled Model Intercomparison  
80 Project Phase 6 (CMIP6) models predict little historical trends for atmospheric dust  
81 loading. This suggests that current climate models have uncertainties in representing  
82 historical global dust emissions, and the climate assessment without considering dust  
83 historical changes is biased.

84       The substantial increase in the reconstructed dust loading can be at least partially  
85 attributed to the anthropogenic impacts on dust emissions (i.e., anthropogenic dust, AD).  
86 It has been noted for a long time that dust emissions are related to anthropogenic  
87 activities (Penner et al., 1994). However, there is no consensus on the definition of AD.  
88 Zender et al. (2004) classified the AD into two categories: (1) those related to  
89 anthropogenic land use change that changes soil surface conditions, and (2) those  
90 modified by anthropogenic climate changes, such as the changes in surface wind, soil  
91 moisture, and precipitation. The first kind of AD includes both direct mechanical  
92 injection of dust caused by anthropogenic activities (e.g., construction, transportation,  
93 and agricultural activities) (Chen et al., 2018) and AD due to wind erosion over the land  
94 surface disturbed by human activities (e.g., deforestation, overgrazing, overcultivation,  
95 inappropriate irrigation practices, and desiccation of rivers and lakes). Previous studies  
96 may only partially consider the above categories of AD.

97       Quantifying the contribution of AD to global dust cycle is highly uncertain.  
98 Modeling and observational estimates of the AD contribution spread in a wide range that  
99 goes from less than 10% to up to 60% (Chen et al., 2018; Ginoux et al., 2012; Huang et  
100 al., 2015; Mahowald et al., 2004; Mahowald & Luo, 2003; Sokolik & Toon, 1996;  
101 Stanelle et al., 2014; Tegen et al., 2004; Tegen & Fung, 1995). One challenge for these  
102 studies lies in the separation of AD from natural dust (ND). Land use datasets are  
103 sometimes used in aid of the separation. Early studies, like Sokolik and Toon (1996),  
104 simply assumed that the AD loading is linearly proportional to the land area converted to  
105 deserts by human activities. More recently, Ginoux et al. (2012) identified dust sources

106 using the Moderate-Resolution Imaging Spectroradiometer (MODIS) frequency-of-  
107 occurrence (FoO) distributions of dust optical depth (DOD) and then attributed AD and  
108 ND sources using the land use data from the History Database of the Global  
109 Environment (HYDE, Klein Goldewijk, 2001) – dust sources with land use exceeds 30%  
110 are AD sources; otherwise they are ND sources. The major AD sources identified in  
111 their study include the Sahel and the Mediterranean coast in North Africa, the north  
112 China plains and Saudi Arabia in Asia, as well as the high plains in North America.  
113 They further estimated the AD emission through applying the source function map  
114 derived from the MODIS FoO data to a global atmospheric model, which showed that  
115 the AD emissions account for 25% of global dust emissions. Moreover, Huang et al.  
116 (2015) combined the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation  
117 (CALIPSO) dust and planetary boundary layer (PBL) retrievals with the MODIS global  
118 land cover type product. By assuming that AD originates from different land cover from  
119 ND and is mostly trapped within PBL, they suggest that AD contributes to around 25%  
120 of global continental dust burden, which is in good agreement with the estimate by  
121 Ginoux et al. (2012). In addition, instead of using observational datasets, Stanelle et al.  
122 (2014) represented anthropogenic sources of dust through the simulated vegetation cover  
123 on each plant function type (PFT) in the land component of a global model. They found  
124 that 10% of dust particles in present day are emitted from anthropogenic (agricultural)  
125 sources.

126 For modeling studies, another open question is how to parameterize AD emission  
127 fluxes. Currently, AD emissions are generally simulated by modifying the ND emission

128 parameterizations for identified AD sources. The threshold of wind friction velocity is a  
129 parameter commonly tuned for AD emissions. Both Stanelle et al. (2014) and Ginoux et  
130 al. (2012) increased the threshold velocity to account for the soil conservation practices  
131 which are employed to reduce the wind erosion. However, other studies decreased this  
132 threshold velocity by assuming that the soil disturbed by anthropogenic activities is more  
133 vulnerable to wind erosion (Chen et al., 2018; Tegen et al., 2004). The above  
134 inconsistency indicates that large uncertainty exists in the understanding of AD  
135 emissions.

136       The Energy Exascale Earth System Model version 1 (E3SMv1) is a global Earth  
137 system model developed by the U.S. Department of Energy (Golaz et al., 2019). The  
138 baseline E3SMv1 does not account for AD emission and predicts a small decreasing  
139 trend in dust burden after 1950 (Zhang et al., 2022), which, like many other CMIP6  
140 models, is not consistent with the increasing trend of dust burden as shown in Kok et al.  
141 (2023). In this study, we develop a new method to parameterize the AD emission and  
142 implement it in E3SMv1. The parameterization uses the fraction of crop PFT from the  
143 land component of E3SMv1. The paper is organized as follows. Section 2 introduces the  
144 E3SMv1 model, our new AD parameterization, and the model experiment setup. Section  
145 3 provides a description of the observational data we use. Section 4 evaluates the new  
146 parameterization against observations, investigates the historical change of AD emission  
147 from PI to PD, and quantifies the direct effective radiative forcing of AD. Finally, we  
148 discuss the uncertainties of our study in Section 5 and summarize the results in Section 6.

## 149 **2 Model**

### 150 **2.1 E3SM model**

151 We use the atmosphere and land components of E3SMv1 (J. Golaz et al., 2019;  
 152 Rasch et al., 2019) in this study. E3SM Atmosphere Model version 1 (EAMv1) includes  
 153 parameterizations for deep convection (Zhang & McFarlane, 1995), cloud microphysics  
 154 (Gettelman & Morrison, 2015), as well as a unified parameterization for cloud  
 155 macrophysics, turbulence, and shallow convection following Cloud Layers Unified by  
 156 Binormals (CLUBB; Bogenschutz et al., 2013; Golaz et al., 2002; Larson & Golaz,  
 157 2005). Atmospheric aerosols are treated through a four-mode version of modal aerosol  
 158 module (MAM4) (Liu et al., 2016; Wang et al., 2020), which predicts the number and  
 159 mass mixing ratios of seven aerosol species (i.e., dust, black carbon, primary organic  
 160 aerosol, secondary organic aerosol, sulfate, sea salt, and marine organic aerosol) in four  
 161 lognormal size modes (Aitken, accumulation, primary carbon, and coarse modes). Dust  
 162 aerosols are carried in the accumulation and coarse modes. The aerosol optical properties  
 163 are parameterized following Ghan and Zaveri (2007), while the dust optical properties  
 164 are updated according to Albani et al. (2014). We note that MAM4 neglects the  
 165 longwave scattering of dust aerosols and only accounts for the longwave absorption as  
 166 well as the shortwave absorption and scattering. Dust aerosols in the model also interact  
 167 with cloud formation through acting as CCN in liquid clouds (Abdul-Razzak & Ghan,  
 168 2000) and INPs in stratiform mixed-phase clouds (Wang et al., 2014) and cirrus clouds  
 169 (Liu et al., 2007; Liu & Penner, 2005). The wet (in-cloud nucleation and below-cloud

170 scavenging) and dry deposition of dust are treated together with the other aerosol species  
171 in the same aerosol mode.

172 The land component in E3SMv1 is the E3SM land model version 0 (ELMv0). It  
173 is modified from the Community Land Model version 4.5 (CLM4.5) (Oleson et al.,  
174 2013). To represent the spatial land surface heterogeneity, each grid cell in ELMv0 is  
175 composed of multiple land units. Each land unit can be further divided into several  
176 columns, such as snow/soil columns. The soil column is composed of up to 15 PFTs  
177 (including 8 types of trees, 3 types of shrubs, 3 types of grass, and one type of crop) plus  
178 bare ground. The vegetation coverage over each PFT is defined by leaf and stem area  
179 indices. The seasonal vegetation changes are based on satellite phenology, which is a  
180 climatology of satellite remote sensing data (Lawrence & Chase, 2007).

## 181 **2.2 Dust emission parameterization in E3SMv1**

182 The dust emission flux is parameterized in ELMv0 following Zender et al. (2003;  
183 hereafter Z03). The total vertical dust emission flux,  $F_d$ , is given by

$$184 \quad F_d = TS_{geo}f_m\alpha Q_s, \quad (1)$$

185 where  $T$  is a global uniformed tuning factor;  $S_{geo}$  is the geomorphic soil erodibility;  $f_m$   
186 is the grid cell fraction of exposed bare soil;  $\alpha$  is the sandblasting mass efficiency; and  
187  $Q_s$  is the total horizontally saltating mass flux.  $S_{geo}$  is a measure of the soil's ability to  
188 produce dust emission for a given meteorological forcing, which is proportional to the  
189 upstream runoff collection area (Zender & Newman, 2003). The factor  $f_m$  is given by

$$190 \quad f_m = (1 - f_{lake} - f_{wetl})(1 - f_{sno})(1 - f_v) \frac{w_{liq,l}}{w_{liq,l} + w_{ice,l}}, \quad (2)$$

191 where  $f_{lake}$ ,  $f_{wetl}$ , and  $f_{snow}$  are the ELMv1's grid cell fractions of lake, wetland, and  
 192 snow cover, respectively;  $w_{liq,l}$  and  $w_{ice,l}$  are the topsoil layer liquid water and ice water  
 193 contents, respectively.  $f_v$  is the vegetation cover fraction that is assumed to increase  
 194 linearly with the leaf and stem area index (LAI),  $\lambda$ , and given by

$$195 \quad f_v = \lambda / \lambda_{thr}, (\lambda \leq \lambda_{thr}). \quad (3)$$

196 Here,  $\lambda_{thr} = 0.3 \text{ m}^2 \text{ m}^{-2}$  is the threshold of LAI above which no dust emission is  
 197 allowed (Mahowald et al., 2006). The LAI is averaged over all the PFTs.

198 The horizontally saltating flux,  $Q_s$ , is given by

$$199 \quad Q_s = \frac{c_s \rho_{atm} u_{*s}^3}{g} \left(1 - \frac{u_{*t}}{u_{*s}}\right) \left(1 + \frac{u_{*t}}{u_{*s}}\right)^2, (u_{*s} > u_{*t}), \quad (4)$$

200 where  $c_s = 2.61$ ;  $\rho_{atm}$  is the surface air density,  $g$  is the gravitational acceleration  
 201 constant;  $u_{*s}$  is the wind friction speed; and  $u_{*t}$  is the threshold wind friction speed for  
 202 saltation.  $u_{*t}$  is proportional to  $f_w$ , which is a factor depending on soil moisture and is  
 203 given by

$$204 \quad f_w = 1, (w \leq w_t), \quad (5)$$

$$205 \quad f_w = \sqrt{1 + 1.21[100(w - w_t)]^{0.68}}, (w > w_t). \quad (6)$$

206  $w$  and  $w_t$  are gravimetric water content of the top soil layer and its threshold,  
 207 respectively. According to Fecan et al. (1999),  $w_t$  is a function of soil's clay fraction  
 208 ( $M_{clay}$ , ranging from 0 to 1):

$$209 \quad w_t = a(0.17M_{clay} + 0.14M_{clay}^2), \quad (7)$$

210 where  $a$  is a tuning parameter and is set to  $1/M_{clay}$  by Z03. A smaller value of  $a$   
 211 indicates a larger effect of soil moisture on  $u_{*t}$ .

212 According to the dust emission size distribution in Z03, 3.2% and 96.8% of the  
 213 total dust emission mass flux are distributed into the accumulation and the coarse aerosol  
 214 modes, respectively, in EAMv1. This is the default setting of the model. We note this  
 215 size distribution leads to an overestimation of dust emission in clay size ( $< 2 \mu\text{m}$   
 216 diameter) (Kok, 2011; Kok et al., 2017).

### 217 **2.3 Parameterization for AD emissions**

218 By default, Z03 parameterization only includes ND emissions. In this study, we  
 219 apply a modified Z03 parameterization to the AD sources to represent AD emissions.  
 220 The fraction of potential AD sources in each grid cell is defined as the exposed bare soil  
 221 fraction of crop PFT ( $f_{m,ant}$ ) in an ELMv0 grid cell.  $f_{m,ant}$  is determined following Eq.  
 222 (2) but only the LAI for the crop PFT is used to calculate the vegetation cover fraction  
 223 ( $f_v$ , see Eq. (3)). This method is similar to Stanelle et al. (2014), where they identified  
 224 the AD sources using LAI on each PFT in the land component of the ECHAM6 model.

225 Two other major modifications are made to the Z03 parameterization when  
 226 applied to the AD sources. First, to increase the impact of soil moisture, the tuning factor  
 227  $a$  in Eq. (7) is reduced from  $1/M_{clay}$  to 1 when calculating the soil water content  
 228 threshold ( $w_t$ ). This modification results in an increase of the threshold wind friction  
 229 speed ( $u_{*t}$ ) used in the calculation of the saltating flux for AD ( $Q_{s,ant}$ ), which is  
 230 consistent with Stanelle et al. (2014) and Ginoux et al. (2012). Second, the AD emission  
 231 is set to zero when soil moisture content is larger than 25% to prevent unrealistic  
 232 emissions from Europe (not shown). With the two modifications above, we allow for the

233 stronger suppression of soil moisture on dust emission than the default parameterization,  
234 which can better simulate dust emissions over cropland.

235 With all these modifications, Eq. (1) is revised to

$$236 \quad F_d = TS_{geo}f_{m,ND}\alpha Q_s + T_{AD}S_{AD}f_{m,AD}\alpha Q_{s,AD}, \quad (8)$$

237 where the first and the second terms on the righthand side represent emission fluxes for  
238 ND and AD, respectively. The ND emission flux is slightly modified compared to Eq.  
239 (1), because the LAI over crop PFT is not included in the calculation of  $f_{m,ND}$  to avoid  
240 double counting.  $T_{AD}$  is the tuning factor for AD.  $S_{AD}$  is the source function for AD,  
241 which is currently set to 1 globally. In summary, we define AD emissions as agricultural  
242 dust emissions from crop PFT, while dust emissions from the other PFTs are considered  
243 as ND emissions.

244 Moreover, to explicitly track natural and anthropogenic dust emissions, we  
245 implement the dust source tagging technique (Shi et al., 2022) in EAMv1 by adding AD  
246 to a separate tracer from ND. With the tagging technique, anthropogenic and natural dust  
247 undergo the abovementioned processes independently from each other.

248 Similar to Stanelle et al. (2014), our modifications physically link the AD  
249 emission to the change of land type and vegetation coverage in the land component of  
250 E3SMv1. By avoiding using an empirical soil source function map that is based on  
251 present-day observations, our approach has the flexibility to simulate AD emissions in  
252 the past and future climate.

## 253 2.4 Experiment setup

254       The experiments we conducted for this study are summerized in Table 1. To  
 255 evaluate the performance of our new parameterization, a control experiment based on the  
 256 standard E3SMv1 model (labeled as CTRL) and an experiment including our  
 257 modifications regarding AD emission and dust tagging (labeled as NEW) were  
 258 performed. For the two experiments, the E3SMv1 model was integrated from January  
 259 2000 to December 2010 at 1° horizontal resolution with 72 vertical layers. The first-year  
 260 results were treated as spin-up and the last ten years (from 2001 to 2010) were used in  
 261 our analysis. The sea surface temperature (SST) is prescribed using the climatology from  
 262 1870 to 2009. The horizontal wind components were nudged to the Modern-Era  
 263 Retrospective Analysis for Research and Applications version 2 (MERRA-2) reanalysis  
 264 data (Gelaro et al., 2017) with a relaxation time scale of 6 h using the linear function  
 265 nudging strategy as described in Sun et al. (2019). The land surface data (including land  
 266 fraction for crop PFT) follows the year 2000 to represent the AD emission in PD  
 267 conditions. The emission for anthropogenic and biomass burning aerosols as well as the  
 268 concentrations of tracer gases (e.g., the greenhouse gases) are prescribed using the data  
 269 of 2000. We note that the MERRA-2, SST, emission, and land use data used for the  
 270 simulations are from different years due to the availability of the datasets, which may  
 271 results in inconsistency. It is also noted that the global dust emission in CTRL and NEW  
 272 were tuned so that the global total dust emission in the two experiments are close to each  
 273 other and the global averaged DOD is within the range of observational estimates  
 274 ( $0.030 \pm 0.005$ ) by Ridley et al. (2016) (See details below in Section 4.1).

Moreover, we conducted another experiments (labeled as NEW\_PI) to estimate the effective radiative forcing of dust due to aerosol-radiation interactions ( $ERF_{ari}$ ) from PI to PD. The setup for the experiment is the same as NEW, except that it uses the land surface data for 1850 to represent the dust emissions in the PI condition. The  $ERF_{ari}$  of dust is calculated following Ghan (2013)'s method with the equation below:

$$ERF_{ari} = \Delta(F - F_{clean}). \quad (9)$$

Here,  $\Delta$  represents the difference between the experiments with dust emissions in PD and PI conditions (i.e., NEW minus NEW\_PI).  $F$  are the all-sky radiative fluxes, while  $F_{clean}$  are the radiative fluxes under no aerosol conditions. A caveat of this method is that different land cover datasets used in NEW and NEW\_PI may impact the estimated  $ERF_{ari}$  through changes in surface albedo. Details regarding  $ERF_{ari}$  are provided in Section 4.3. In addition, we note the effective radiative forcing of dust due to aerosol-cloud interactions ( $ERF_{aci}$ ) is not estimated in this study because the surface albedo differences between PI and PD largely impact the estimate of  $ERF_{aci}$ .

### 3 Observations

#### 3.1 MIDAS

The ModIs Dust AeroSol (MIDAS) dataset (Gkikas et al., 2021) provides daily DOD at 550nm at  $\sim 0.1^\circ$  horizontal resolution on a global scale. This dataset derives DOD by combining aerosol optical depth (AOD) from MODIS-Aqua (Collection 6.1; Level 2) with DOD-to-AOD ratios from MERRA-2 reanalysis data. In our study, we use

295 the data from 2003 to 2010 and process the original data to an annual mean DOD at 1°  
296 horizontal resolution. The processed MIDAS DOD is compared with annual mean  
297 simulated DOD from 2001 to 2010.

### 298 **3.2 Dust deposition flux measurements**

299 The dust deposition flux dataset, which consists of 84 stations, was compiled by  
300 Huneus et al. (2011). This compilation includes measurements from Ginoux et al.  
301 (2001), Mahowald et al. (2009), Mahowald et al. (1999), and the Dust Indicators and  
302 Records in Terrestrial and Marine Paleoenvironments database (Kohfeld & Harrison,  
303 2001; Tegen et al., 2002). In general, the observation sites are located at relatively  
304 remote regions. It is noted that the measurements were collected during the late 20<sup>th</sup>  
305 centuries, while we compare them against modelling results over the period 2001-2010  
306 to evaluate the model from a climatological perspective. Systematic errors are  
307 introduced here because the period of the simulation does not coincident with that of the  
308 measurements. Moreover, we use simulated dust over the whole size range ( $< 10 \mu\text{m}$ ) for  
309 the comparison whereas the size range of the measurements is unknown, which is likely  
310 to be another source of uncertainties in the comparison. Also, comparing model results at  
311  $\sim 100$  km resolution with deposition flux data measured at stations leads to representative  
312 biases (same source of bias also exists for the ground-based measurements introduced in  
313 Sections 3.3 and 3.4 below).

### 314 **3.3 AERONET AOD**

315       The Aerosol Robotic NETwrok (AERONET) (Holben et al., 1998) conducts sun  
316 photometer sky radiance measurements that are inverted to produce aerosol properties  
317 across the world. Following Kok et al. (2014), we process the level 2.0 quality assured  
318 AOD from version 2 direct sun algorithm during the simulation time period (2001 to  
319 2010) at 40 “dust-dominated” sites, which include 16 in North Africa, 11 in Middle East,  
320 6 in rest of Asia, 3 in Australia, and 4 in Atlantic. Most of the sites locate at regions  
321 close to the AD sources identified by Ginoux et al. (2012). It is noted that the  
322 AERONET AOD measurements are biased towards clear-sky conditions due to the  
323 cloud-screening procedure (Smirnov et al., 2000).

### 324 **3.4 IMPROVE dust and aerosol concentrations measurements**

325       The Interagency Monitoring of Protected Visual Environments (IMPROVE;  
326 Malm et al., 1994) network operates filter based surface aerosol measurements across  
327 the United States. Here, we use the fine dust (FD) and coarse aerosol mass (CM)  
328 concentrations from the IMPROVE network during the simulation period (2001 to 2010).  
329 The observed FD concentrations are estimated from an empirical relationship with the  
330 isotopic mass concentrations of aluminium, silicon, calcium, iron, and titanium (Malm et  
331 al., 1994). They only include dust particles with diameter smaller  $2.5\ \mu\text{m}$  and are  
332 compared with simulated dust concentrations at the same size range. The CM  
333 concentrations are determined by the difference of the measured PM<sub>10</sub> and PM<sub>2.5</sub> mass.  
334 They are compared with simulated total aerosol mass in the same size range. Previous

335 studies use CM as a proxy for dust (e.g., Wu et al., 2018). A CM speciation study at 9  
 336 IMPROVE sites that represent the continental US found that crustal minerals (i.e., dust)  
 337 accounts for 34% to 76% of the CM concentrations, which makes dust the single largest  
 338 contributor to CM in all the stations except the Mount Rainier site (Malm et al., 2007).  
 339 However, other aerosols, like carbonaceous aerosols, nitrate, and sulfate, may also  
 340 contribute to CM. Therefore, to further eliminate the contribution from non-dust aerosols,  
 341 we select the CM data only when the simulated dust accounts for more than 90% of the  
 342 total aerosol mass for the comparisons. The location of the IMPROVE sites are shown in  
 343 Figure S1. In total, we select 194 and 67 stations for FD and CM comparisons,  
 344 respectively.

## 345 **4 Results**

### 346 **4.1 Present-day dust emission and global dust cycle**

347 Figure 1 shows the simulated dust emission fluxes from the NEW and CTRL  
 348 experiments at PD. The global total dust emission flux from NEW is  $4263 \text{ Tg yr}^{-1}$ , with  
 349 ND and AD accounting for  $3695 \text{ Tg yr}^{-1}$  and  $567 \text{ Tg yr}^{-1}$ , respectively. The AD emission  
 350 contributes 13.3% to the total dust emission, which is lower than the estimate (25%) by  
 351 Ginoux et al. (2012) but comparable with the estimate (10%) from Stanelle et al. (2014).  
 352 The AD emission sources in NEW locate in the Great Plains of the North America, the  
 353 Sahel and the Atlas Mountains of North Africa, East European Plain and Central Asia,  
 354 highlands of Saudi Arabia in the Middle East, Pakistan and North India in South Asia,

355 North and Northeast China plains in East Asia, and the southwest of Australia (Figure  
 356 1d). These AD sources are corroborated with the sources identified by Ginoux et al.  
 357 (2012) using the MODIS data, except those located in East Europe and northern part of  
 358 Central Asia. One possible reason for this is that the MODIS data they utilized only  
 359 extends to 50°N and does not include East Europe and northern part of Central Asia. We  
 360 note that previous observational studies (e.g., Verheijen et al., 2009) have reported  
 361 agricultural dust emissions over East Europe, which supports our results. The Central  
 362 Asia AD emissions were also identified by Stanelle et al. (2014) that agrees with our  
 363 results. Overall, the global spatial distribution of the simulated AD emissions is largely  
 364 correlated with the crop PFT fraction (Figure 1e) but also related to the vegetation  
 365 coverage, soil moisture, and surface wind speed. The total emission flux from NEW  
 366 ( $4263 \text{ Tg yr}^{-1}$ ) is comparable with that from CTRL ( $4106 \text{ Tg yr}^{-1}$ ) due to the model  
 367 tuning of global DOD mentioned in Section 2.4, while the dust sources simulated by  
 368 CTRL are mostly classified as the ND ones in NEW. This indicates that the dust  
 369 emissions are redistributed in NEW by lowering the ND emissions and representing the  
 370 AD sources compared to CTRL.

371 Table 2 summarizes the global dust budget of CTRL and NEW experiments,  
 372 while the spatial distributions of dust optical depth (DOD) are shown in Figure 2. The  
 373 global and annual mean DOD from the NEW experiment is 0.028, which is within the  
 374 observational estimate ( $0.030 \pm 0.005$ ) by Ridley et al. (2016). The global distribution of  
 375 AD DOD correlates with the AD emissions (Figure 1d), with the maximum values in  
 376 East Sahel, the Atlas Mountain, North India, and North China. The global and annual

mean DOD from NEW is close to that from CTRL (0.029) because of the tuning strategy applied to the global total dust emission. However, the spatial distributions of total DOD are slightly different in the two experiments (Figure 2e) – the NEW experiment simulates larger DOD at regions close to AD sources but smaller DOD over major ND sources (e.g., Sahara and Gobi Desert), which is consistent with the aforementioned redistribution of dust emission in NEW. The total dust burden in NEW is 22.0 Tg, which is within the range of the AeroCom (Aerosol Comparisons between Observations and Models) models (8 to 30 Tg; [Huneeus et al., 2011](#)). The total dust burden from NEW is also close to that from CTRL. The contributions of AD to total DOD and total dust burden in NEW are 10.7% and 10.9%, respectively, which are slightly smaller than the contribution (13.3%) of AD to total dust emission because of the shorter lifetime of AD (1.52 days) than that of ND (1.94 days). This indicates a faster removal of AD than ND from the atmosphere, likely associated with the fact that AD is emitted from cropland and trapped within PBL whereas ND from deserts can be uplifted above PBL (e.g., by cold fronts) during emissions and undergo the long-range transport (Huang et al., 2015). We note that the dry removal rate (i.e., dry deposition flux divided by burden) for AD ( $188 \text{ yr}^{-1}$ ) is much larger than that for ND ( $147 \text{ yr}^{-1}$ ), which indicates a stronger dry deposition of AD that is corroborated with its possibly weaker vertical transport. The lifetime of total dust from NEW (1.88 days) is slightly shorter than that from CTRL (1.94 days), while the lifetime of ND from NEW (1.94 days) is the same as that from CTRL.

## 398 **4.2 Model evaluation**

399       The comparisons between simulated DOD and the MIDAS dataset are shown in  
 400 Figure 3. Overall, NEW and CTRL perform similarly when comparing with MIDAS.  
 401 The misrepresentations of simulated DOD are mainly caused by biases in the ND  
 402 emissions and atmospheric processes that affect dust transport and deposition. For  
 403 example, both CTRL and NEW show underestimations over West Sahara and  
 404 overestimations over East Sahara, which are known biases related to the geomorphic  
 405 source function used by the Z03 dust emission parameterization (Wu et al., 2020).  
 406 However, regional changes related to the AD emissions are also presented. The CTRL  
 407 experiment has strong low biases over North India, which is turned into high biases after  
 408 including the AD emissions in NEW (Figure 1d). The newly represented AD sources in  
 409 North China also result in an overprediction in NEW, which is not shown in CTRL. The  
 410 AD emissions also lead to a larger DOD in NEW than CTRL over the Bay of Bengal,  
 411 Southeast Asia, and South China (Figure 2e), which reduces the low biases over these  
 412 regions or even turn them into high biases in NEW. In addition, the underprediction over  
 413 the central US in CTRL is slightly improved in NEW, since the NEW experiment  
 414 predicts larger DOD over there due to the local AD emissions (Figure 2e).

415       The NEW and CTRL experiments also perform similarly well in the comparison  
 416 with the global dust deposition flux dataset (Figure 4) – both experiments show  
 417 reasonably good agreement with observations with a correlation coefficient ( $R$ ) of 0.86.  
 418 One major reason for the similar performance is that most of the deposition  
 419 measurements were conducted at remote regions. Since the AD sources are generally

420 close to the ND sources, the impact of different source locations is minimalized when  
421 dust aerosols reach remote regions after the long-range transport.

422       The impact of newly added AD emissions becomes more noticable when moving  
423 to the regions close to dust sources. Figure 5 shows the simulated AOD in CTRL and  
424 NEW experiments compared with the AERONET AOD at these stations. The  
425 comparison of the AOD seasonal cycle at each station is shown in Figure S2. We note  
426 that many of these stations are significantly influenced by ND because they are located  
427 close to the major ND sources. Despite of this, including AD sources in NEW still  
428 obviously improves the agreement with observations as compared to CTRL – the overall  
429 correlation of the comparison increases from 0.85 in CTRL to 0.90 in NEW, while the  
430 magnitude of the mean bias (MB) reduces by half in NEW. The most significant  
431 improvement occurs in Asia, where the underestimation of AOD is reduced by nearly 10  
432 times (from -0.109 to -0.011). This is mainly due to the newly simulated AD sources in  
433 North India that turn the underestimation at Kanpur and Jaipur stations into slight  
434 overestimation (panel a3 and a4 in Figure S2). This change is consistent with the  
435 MIDAS comparison in North India (Figure 3). These two stations show large high biases  
436 during late spring and early summer in the NEW experiment, which possibly indicates a  
437 wrong seasonal cycle of AD emissions in North India. In addition, the underprediction of  
438 the AOD in North Africa is also slightly improved in NEW. We notice that the simulated  
439 AD DOD in NEW tends to peak between January and April over the Sahel regions  
440 (panel c1, c5, c7-c11, c14, and c16 in Figure S2), which may be linked to the low LAI  
441 over cropland during this time. As a result, the NEW experiment shows improvement

442 during early spring at several stations in Sahel, like Ouagadougou, Ilorin, and Djougou  
443 (panel c5, c7, and c10 in Figure S2, respectively).

444 Figure 6 shows the comparison of simulated surface FD and CM concentrations  
445 with measurements from the US IMPROVE network. Since the network stations are  
446 mostly in considerable distances from the major ND sources, the impacts of AD  
447 emissions are profound. Including AD in the NEW experiment results in an  
448 overprediction of simulated FD (MB changes from  $-0.10 \mu\text{g m}^{-3}$  in CTRL to  $0.40 \mu\text{g m}^{-3}$   
449 in NEW), which makes the comparisons between model and observation worse (R  
450 decreases from 0.685 to 0.520). The high biases in NEW mainly occur at regions close  
451 to AD sources that have relatively high FD concentrations, whereas the NEW  
452 experiment outperforms the CTRL experiment at relatively remote regions where the  
453 simulated FD concentrations is less than  $0.3 \mu\text{g m}^{-3}$ . In contrast, the NEW experiment  
454 shows obvious improvements in simulating CM concentrations, which is evident by an  
455 increase in R from 0.36 to 0.48 and a reduction in the magnitude of MB from  $-3.23 \mu\text{g}$   
456  $\text{m}^{-3}$  to  $-0.44 \mu\text{g m}^{-3}$  as compared to the CTRL experiment. The inconsistency in the  
457 comparisons of FD and CM concentrations may be due to the overestimation of dust  
458 emissions in clay size (Kok, 2011) in E3SMv1.

459 Overall, the above evaluations validate our new parameterization's ability to (1)  
460 simulate global dust cycle comparably well as the baseline model and (2) capture the AD  
461 sources reasonably well as indicated by obvious regional improvements. Next we will  
462 use our AD parameterization to further examine the climate impacts of AD.

### 463 4.3 Historical change of dust and the $ERF_{\text{ari}}$

464 In this section, we examine the historical change of dust emission and the  
 465 consequent dust  $ERF_{\text{ari}}$  due to the land cover change from PI to PD. The dust emissions  
 466 under PI and PD land cover are simulated from NEW\_PI and NEW experiments,  
 467 respectively. The dust budget from NEW\_PI is shown in Table 2, while Figure 7a and 7b  
 468 shows the global distributions of ND and AD emissions in the PI land cover condition.  
 469 The total dust emission increases by  $495 \text{ Tg yr}^{-1}$  (13.1%) from PI to PD, accompanied by  
 470 a 11.7% increase in the global total dust burden. We note this increase is smaller than the  
 471 estimate (24.5%) by Stanelle et al. (2014), because they considered the impact of climate  
 472 change other than that the impact of land use change. The increase in dust emission is  
 473 dominated by a  $347 \text{ Tg yr}^{-1}$  increase in the AD emission – specifically, the AD emission  
 474 increases by 158% from  $220 \text{ Tg yr}^{-1}$  to  $567 \text{ Tg yr}^{-1}$  from PI to PD. The AD emission  
 475 increases over all the AD sources globally from PI to PD (Figure 7d), due to the  
 476 agricultural expansion that is reflected by the increase of cropland fraction (Figure 7e  
 477 and Figure 1e). The ND emission also slightly increases (by less than 5%) from PI to PD  
 478 (Figure 7c). One possible reason is that the increase in cropland consumes forest and  
 479 grassland, which reduces the grid-mean LAI and thus exposed more bare soil as  
 480 potential ND sources (i.e.,  $f_{m,ND}$  increases in Eq. (8) because LAI decreases in Eq. (3)).  
 481 The meteorology changes (e.g., winds and precipitation) due to land use change may  
 482 also contribute to the regional changes in the ND emission. Overall, the impact of land  
 483 use change on ND is much smaller than that on AD. However, it is worth noting that

484 same soil erodibility map is used in the ND emission parameterization for the PI and PD  
485 conditions, which may reduce the sensitivity of ND emissions to the land use change.

486 Finally, we quantify the all-sky TOA  $ERF_{ari}$  of dust due to the land cover change  
487 from PI to PD (Figure 8). The increase in total dust emission induces a negative  
488 shortwave  $ERF_{ari}$  of  $-0.05 \text{ W m}^{-2}$  and a positive longwave  $ERF_{ari}$  of  $0.009 \text{ W m}^{-2}$  (Figure  
489 8a-b), which are due to more scattering of solar radiation and more absorption of  
490 longwave radiation by dust in PD than PI, respectively. The statistically significant  
491  $ERF_{ari}$  of dust are mostly found near the AD sources, indicating a dominant contribution  
492 of AD. We also note that the moderately positive shortwave  $ERF_{ari}$  (Figure 8a) over the  
493 mid-latitude regions in North America and Eurasia is likely related to surface albedo  
494 change because of the deforestation in PD, instead of changes in dust. The resulting net  
495  $ERF_{ari}$  of dust is  $-0.041 \text{ W m}^{-2}$  from PI (1850) to PD (2000) (Figure 8c). This is  
496 substantial compared to the IPCC AR6 estimate of total aerosol  $ERF_{ari}$  ( $-0.3 \pm 0.3 \text{ W m}^{-2}$ )  
497 from 1750 to 2014, which highlights the important role of dust from anthropogenic  
498 land cover change in the regional and global climate changes.

499 In addition, we estimate the clear-sky TOA  $ERF_{ari}$  of dust as shown in Figure S3,  
500 which are  $-0.071$ ,  $0.011$ , and  $-0.06 \text{ W m}^{-2}$  for shortwave, longwave, and net radiation,  
501 respectively. Our estimate is in good agreement with the clear-sky dust  $ERF_{ari}$  ( $-0.05 \text{ W}$   
502  $\text{m}^{-2}$ ) due to anthropogenic land cover change from Stanelle et al. (2014).

## 503 **5. Discussion**

504 In this study, we predict a 11.7% increase in global dust burden due to the land  
505 cover change from PI to PD (Table 2). This increase is higher than most of the CMIP6  
506 models included in the study by Kok et al. (2023), whereas it is still smaller than the  
507 increase ( $55 \pm 30\%$ ) shown by the reconstruction data. Below we provide several  
508 possible explanations.

509 The AD emission parameterization developed in our study only accounts for the  
510 AD produced from wind erosion over the cropland. The wind erosion from other land  
511 types, like pastureland, and direct AD emission due to anthropogenic activities (e.g.,  
512 construction, traffic, and agricultural practices with heavy equipments) are not included.  
513 This indicates that the AD emission in the PD condition may be underestimated. Since  
514 anthropogenic activities and land use changes are more intense in PD than PI, it is likely  
515 that our estimate of the historical dust emission increase is also underpredicted.  
516 Moreover, we only examine the effect of land use changes on dust emissions, while the  
517 climate change factors (e.g., changes in surface wind and soil moisture due to  
518 anthropogenic climate change) are ignored. Stenelle et al. (2014) noted that  
519 anthropogenic climate change is almost equally important in the increase of historical  
520 dust emission as compared to the anthropogenic land use change. A regional study also  
521 found that climatic factors are the main driver of recent decline of dust activity in East  
522 Asia, while vegetation cover change due to land use managements plays only a minor  
523 role (Wu et al., 2022). This indicates that the dust change from PI to PD estimated in our  
524 study may be biased low without considering the impact of climate change. If the above

525 uncertainties are well addressed, the increase of dust emission from PI to PD may be  
526 enlarged, which better matches the estimate by Kok et al. (2023). In this case, the  
527 magnitude of  $ERF_{\text{ari}}$  of dust is likely to increase, which emphasizes the important  
528 contribution of dust to total anthropogenic aerosol radiative forcing.

529         Moreover, this study focuses on the direct radiative forcing of AD, while its  
530 indirect forcing is also of great interest. Dust aerosols are efficient INPs that can  
531 influence the phase partition of mixed-phase clouds (Shi & Liu, 2019), which have  
532 important implications on climate feedback (Murray et al., 2021). In particular,  
533 agricultural dust was found to have distinct ice nucleating ability compared with  
534 mineral dust from desert (ND) at warm temperatures (Steinke et al., 2016), which  
535 indicates that AD and ND may have different impacts on low-level mixed-phase clouds.  
536 Future studies are needed to investigate these topics.

537         In addition, our AD parameterization is simplified, because it only relates the AD  
538 emissions to crop land use. In reality, other factors, like types of crops and agricultural  
539 practices, may also have an impact of AD emission. In our future work, we will  
540 incorporate our AD parameterization with an interactive crop model to take into account  
541 these aspects more comprehensively.

542         Finally, in addition to their climate impacts, dust aerosols may substantially  
543 influence the air quality and human health. The 1930s Dust Bowl in the Southern Great  
544 Plains of North America, which is partially due to poor agricultural practices, resulted in  
545 increasing death and illness from acute respiratory infections (Worster, 2004). Moreover,  
546 a recent study finds that anthropogenic dust from urbanization worsens non-dust air

547 pollution through inducing surface radiative cooling that reduces the planetary boundary  
 548 layer height in urban regions (Xia et al., 2022). A detailed analysis is needed to closely  
 549 evaluate the contribution of AD to human health effects, which is beyond the scope of  
 550 this paper. Here, we use population-weighted surface AD and ND concentrations in the  
 551 PM<sub>2.5</sub> size range (PWAD<sub>PM<sub>2.5</sub></sub> and PWND<sub>PM<sub>2.5</sub></sub>) as a simple metric to broadly  
 552 characterize their human-health-relevant impacts. As shown in Figure 9, the population  
 553 weighted surface concentrations have high values over the densely populated regions.  
 554 The contribution of PWAD<sub>PM<sub>2.5</sub></sub> to total global mean population-weighted surface dust  
 555 concentration is 27.6%, which is more than twice of that before the population weighting  
 556 is applied. This indicates that the AD emission influences human health more efficiently  
 557 than the ND emission, mainly because the AD sources are located closer to human  
 558 habitation.

## 559 **6. Conclusions**

560 In this study, we developed a parameterization to account for the AD emissions  
 561 in E3SMv1, which physically links AD emissions to the crop PFT fraction used in the  
 562 land component of E3SMv1. According to our new parameterization, the global and  
 563 annual AD emission is 567 Tg yr<sup>-1</sup> in the PD condition, which contributes 13.3 % to the  
 564 total dust emission. The major AD sources locate at the Great Plains in the North  
 565 America, the Sahel and the Atlas Mountains in North Africa, East European Plain and  
 566 Central Asia, highlands of Saudi Arabia in Middle East, Pakistan and North India in  
 567 South Asia, North and Northeast China plains in East Asia, and the southwest of

568 Australia. The distribution of the AD sources from our parameterization generally agrees  
569 with the sources identified by Ginoux et al. (2012). The contribution of AD to the global  
570 DOD and dust burden are both about 11 %, which are slightly less than the AD  
571 contribution to the total dust emission, indicating a slightly shorter lifetime of AD than  
572 that of ND. We performed model evaluations against satellite retrievals and ground-  
573 based observations, which demonstrates the new parameterization's ability to represent  
574 AD emissions and global dust cycle reasonably well. We also found that AD can impact  
575 air quality and human health more efficiently than ND likely due to the proximity of AD  
576 sources to human habitation.

577       We examined the historical change of dust emission from PI to PD. We found  
578 that total dust emission increases by 13.1 % from 1850 to 2000, which is dominated by  
579 the increase in AD emission due to the expansion of cropland from PI to PD. As a result,  
580 atmospheric dust burden increases by 11.7 %. Based on this, we estimated the all-sky  
581 TOA  $ERF_{\text{ari}}$  of dust to be  $-0.041 \text{ W m}^{-2}$  from 1850 to 2000. This is more than 10 % of  
582 the total anthropogenic aerosol  $ERF_{\text{ari}}$  ( $-0.3 \pm 0.3 \text{ W m}^{-2}$ ) from 1750 to 2014 estimated  
583 by the IPCC AR6 report, which highlights the important role of dust in the regional and  
584 global climate change. Considering the anthropogenic land use change is predicted to  
585 continue in the future (Hurtt et al., 2020), more studies are needed to investigate the  
586 impact of dust as a forcing agent to the future climate.

 862

863 **Table 1. Experiments conducted in this study.**

Experiment	Description
CTRL	Standard configuration of E3SMv1.
NEW	A simulation including our new parameterization for AD emissions and the dust tagging technique to track AD and ND emissions.
NEW_PI	Same as New, but use 1850 land surface dataset

864

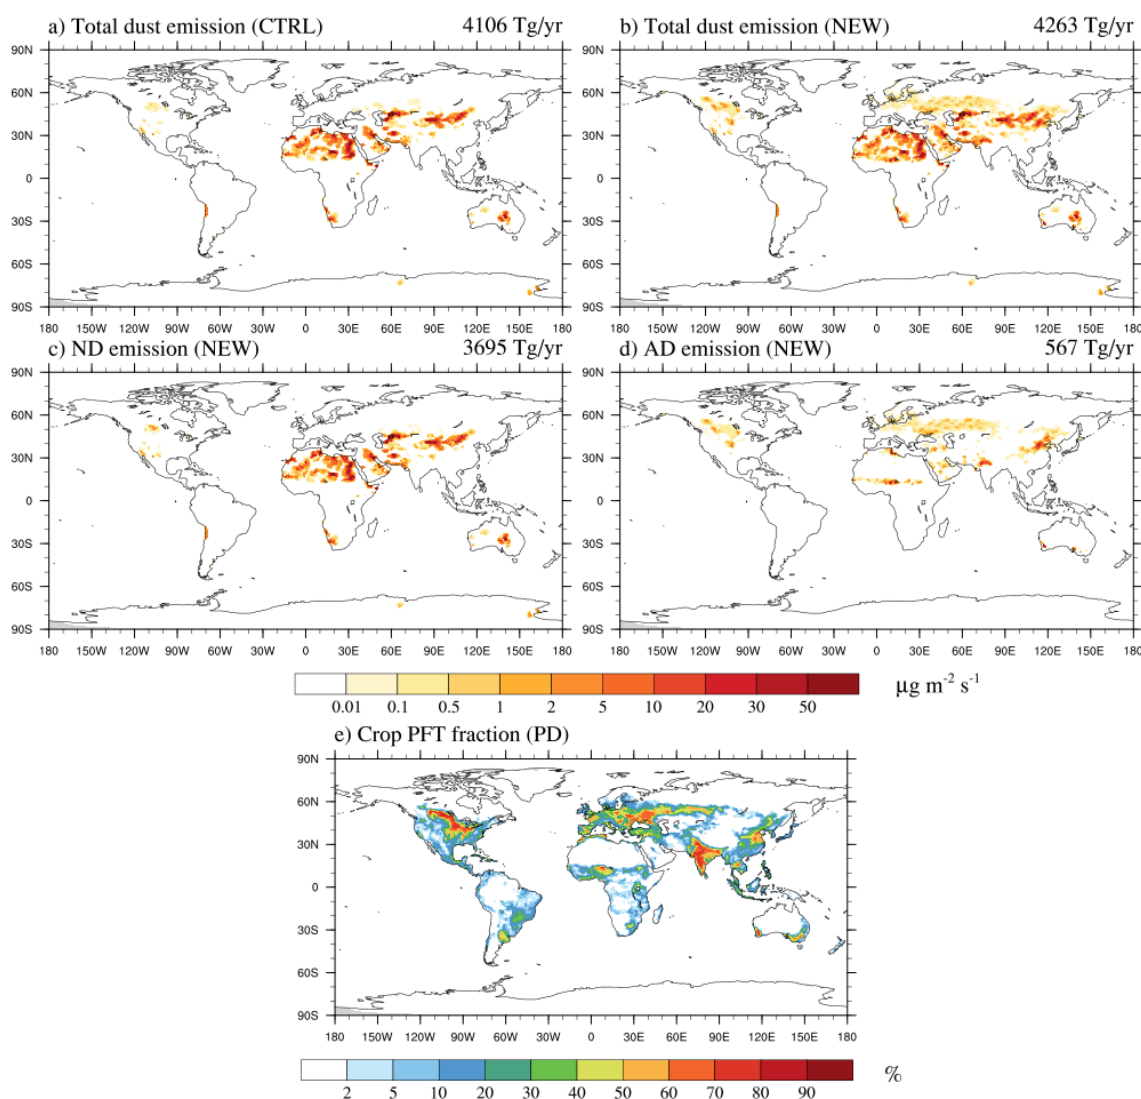

865

866 **Table 2. Global dust budget.**

	CTRL	NEW			NEW_PI		
		Total	ND	AD	Total	ND	AD
Emission (Tg yr <sup>-1</sup> )	4106	4263	3695	567	3768	3548	220
DOD	0.029	0.028	0.025	0.003	0.025	0.024	0.001
Burden (Tg)	21.9	22.0	19.6	2.4	19.7	18.8	0.8
Lifetime (day)	1.94	1.88	1.94	1.52	1.91	1.94	1.40
Dry deposition (Tg yr <sup>-1</sup> )	3183	3336	2884	452	2945	2770	175
Wet deposition (Tg yr <sup>-1</sup> )	922	926	810	115	822	777	45

867

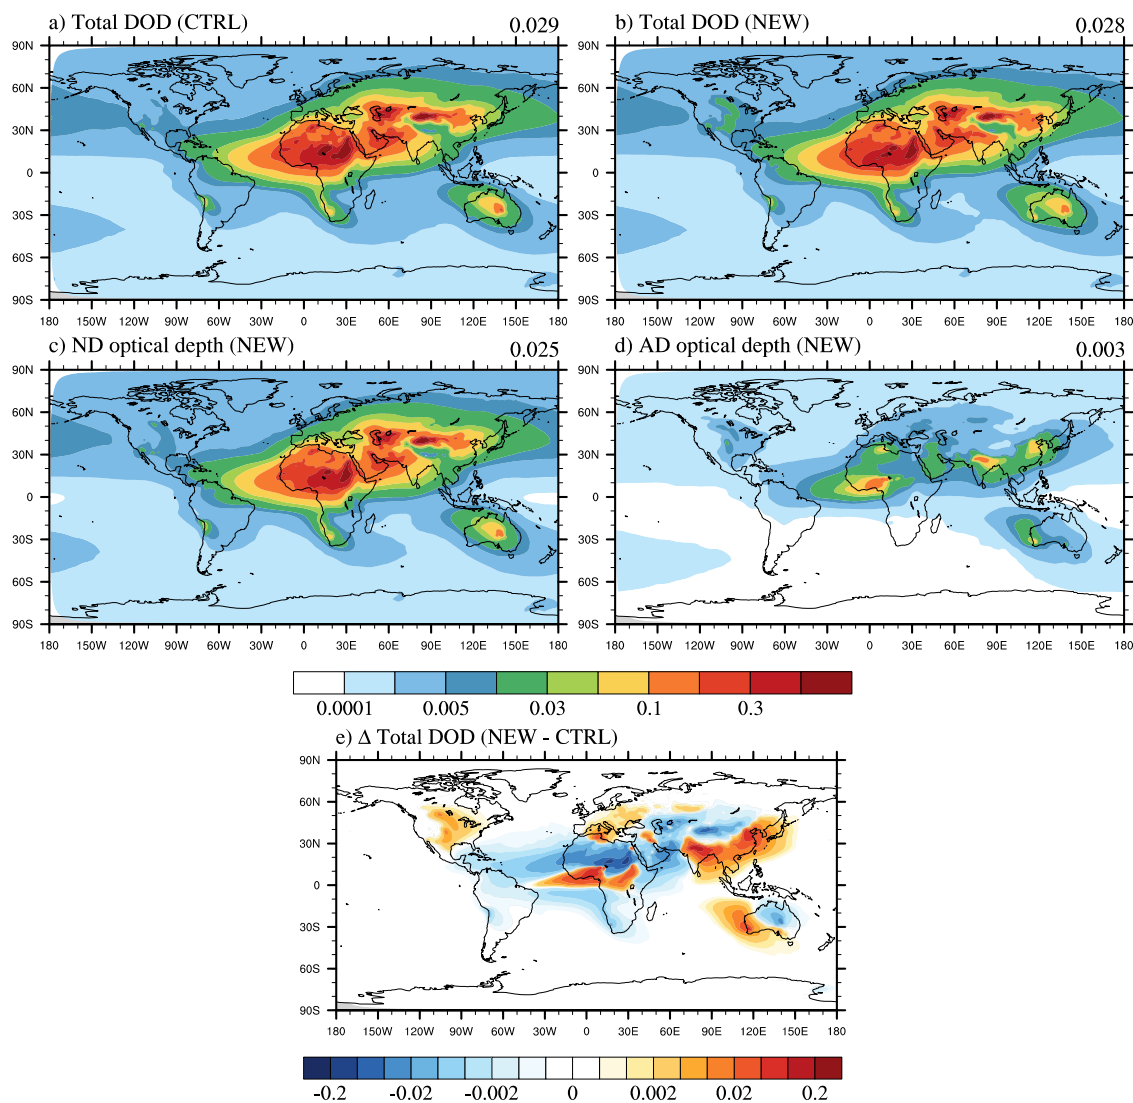

868

869

870 **Figure 1.** Spatial distribution of annual mean dust emission fluxes in the PD conditions.  
 871 Panel a) and b) shows the total dust emission fluxes from CTRL and NEW experiments,  
 872 respectively. Panel c) and d) shows the ND and AD emissions from the NEW  
 873 experiment, respectively. The numbers in panel a)-d) are total global dust emission  
 874 fluxes. The percentage fraction of crop PFT on each grid cell used is shown on panel e),  
 875 which is the same in CTRL and NEW experiments.

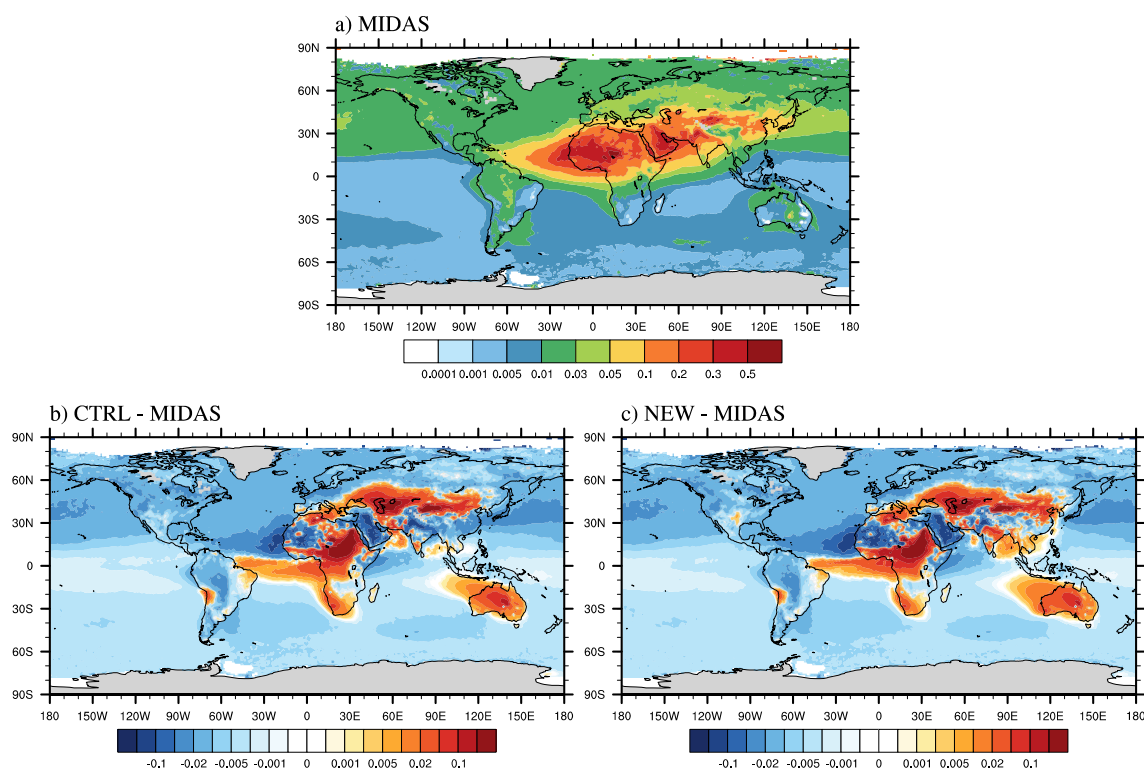

876

877

878 **Figure 2.** Spatial distributions of global annual mean DOD in PD condition. Panel a)  
 879 and b) shows the total DOD from NEW and CTRL experiments, respectively. Panel c)  
 880 and d) shows the ND and AD DOD from NEW, respectively. Panel e) denotes the total  
 881 DOD difference between NEW and CTRL. The numbers on panel a) to d) are global  
 882 averaged DOD.

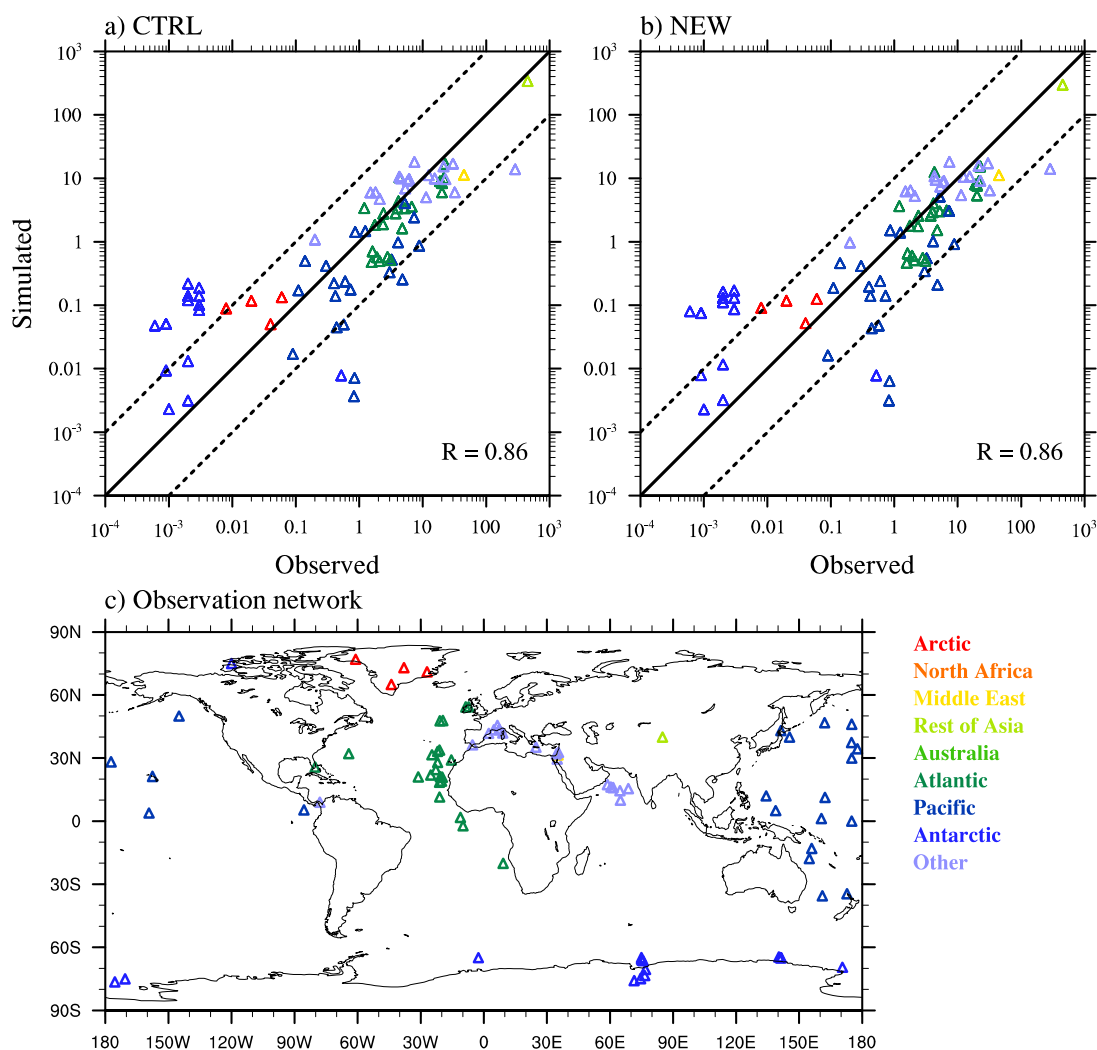

883

884

885 **Figure 3.** Comparison of simulated DOD with the MIDAS dataset. Observations are  
 886 shown in Panel a). Panel b) and c) show the differences between CTRL and NEW  
 887 experiments and MIDAS dataset, respectively.

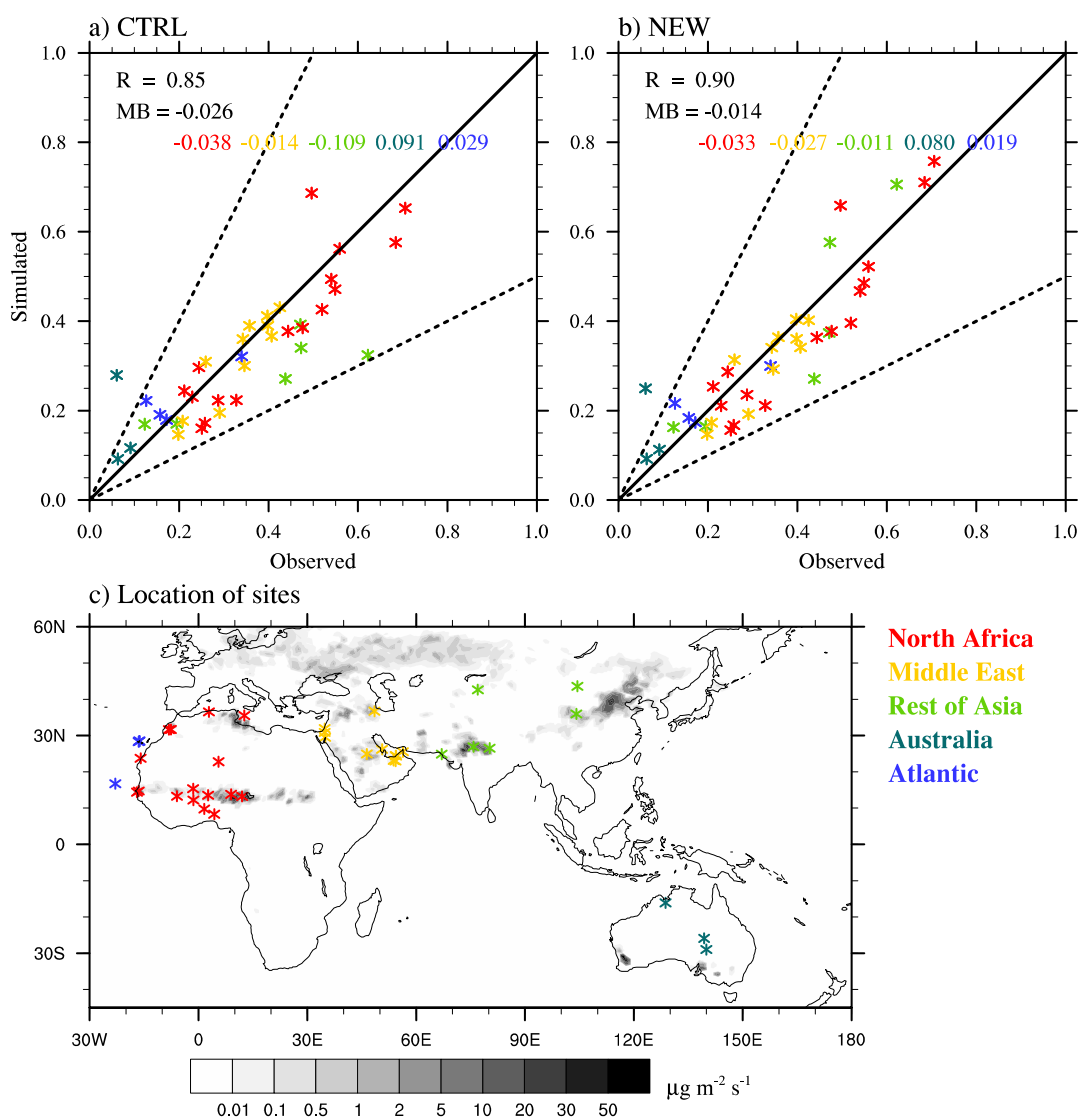

888

889

890 **Figure 4.** Comparisons of observed dust deposition fluxes with modeling results from a)  
 891 CTRL and b) NEW. Solid lines represent 1:1 comparison, while dashed lines represent 1  
 892 order of magnitude differences. The correlation coefficient ( $R$ ) is shown on each  
 893 comparison. The locations of the measurements are shown in panel c). The stations are  
 894 grouped by regions using different colors.

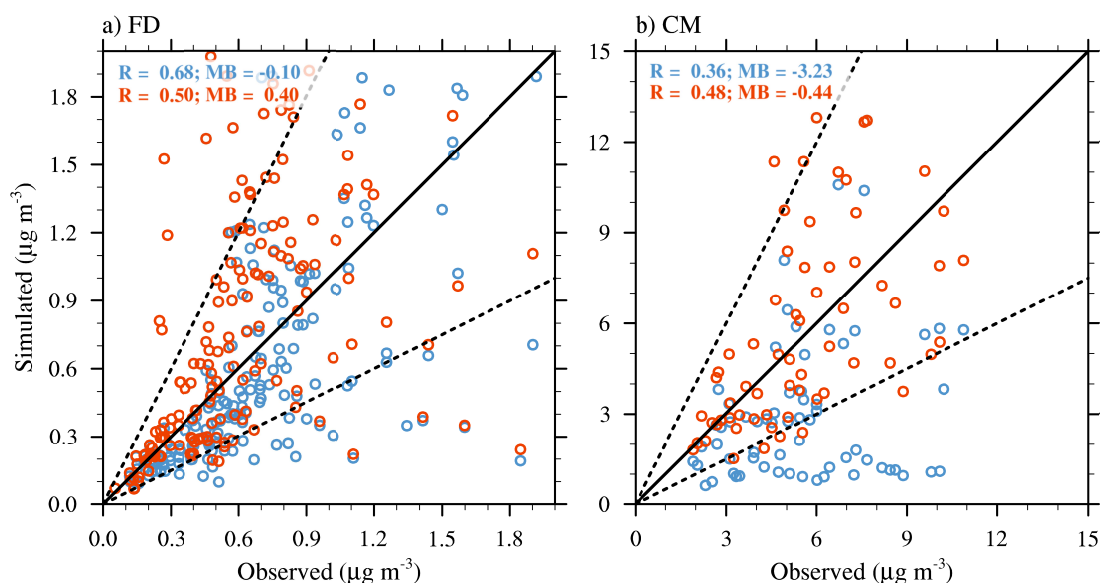

895

896

897 **Figure 5.** Comparisons of AERONET measured AOD and simulated AOD from a)  
 898 CTRL and b) NEW experiments at 40 stations. Solid lines represent 1:1 comparison,  
 899 while dashed lines mark a factor of two differences. The correlation ( $R$ ) and mean bias  
 900 ( $MB$ ) between modeling results and observations are shown in black on the two panels.  
 901 The AERONET stations are grouped regionally and classified by different colors. The  
 902  $MB$  for various regions are also shown in corresponding colors. The locations of the  
 903 sites are shown in panel c). The gray contours on panel c) are the annual mean (year  
 904 2001 to 2010) simulated AD emission fluxes from NEW.

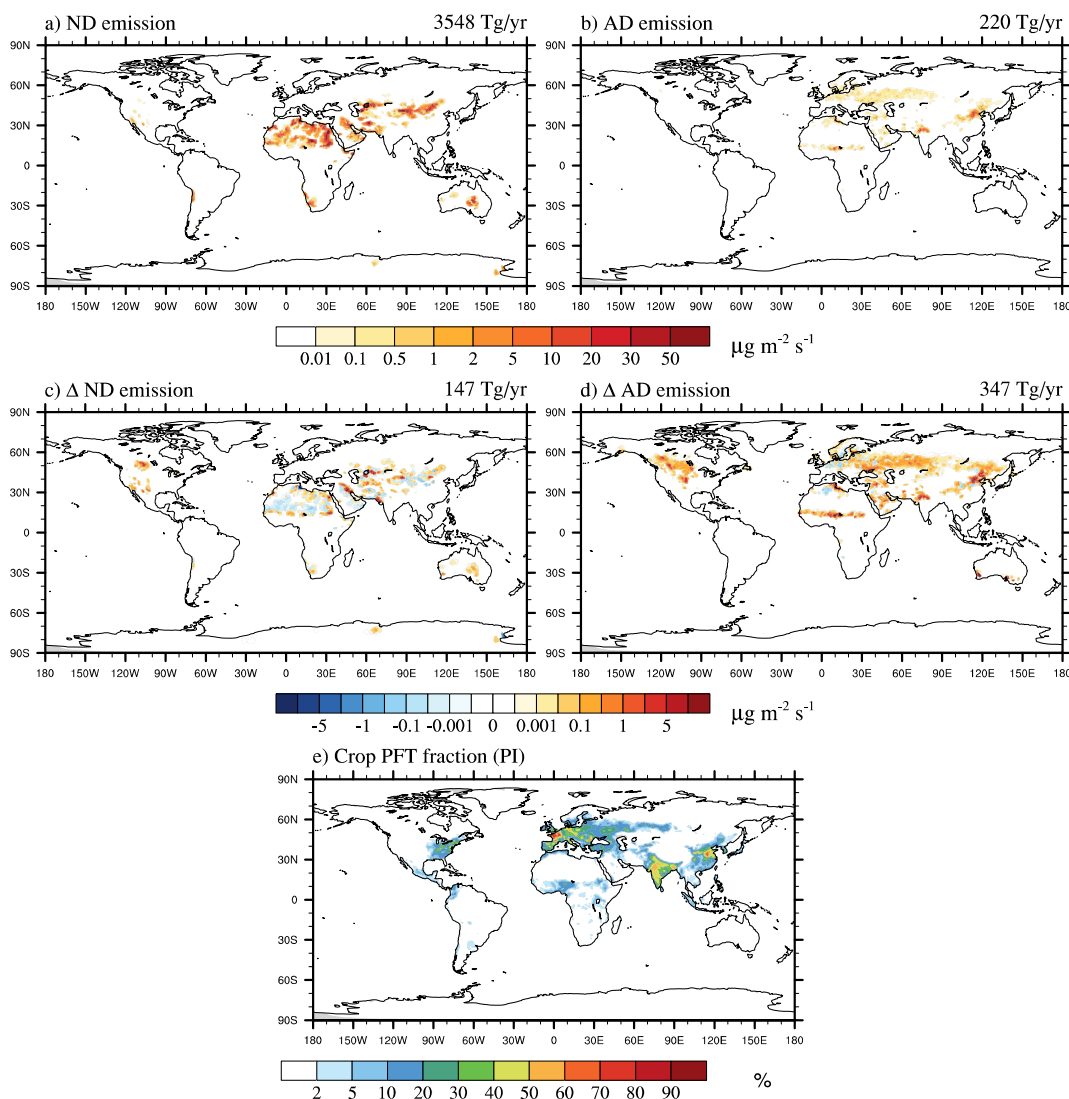

905

907

913 **Figure 6.** Comparisons of a) FD mass concentrations and b) CM concentrations from the  
 914 US IMPROVE network with modeling results from 2001 to 2010. Blue scatters are from  
 915 the CTRL experiment, while orange scatters are from the NEW experiment. Solid lines  
 916 represent 1:1 comparison, while dashed lines mark a factor of 2 differences. R and MB  
 917 ( $\mu\text{g m}^{-3}$ ) of the comparisons are provided. The locations of the measurements are shown  
 918 in Figure S1.

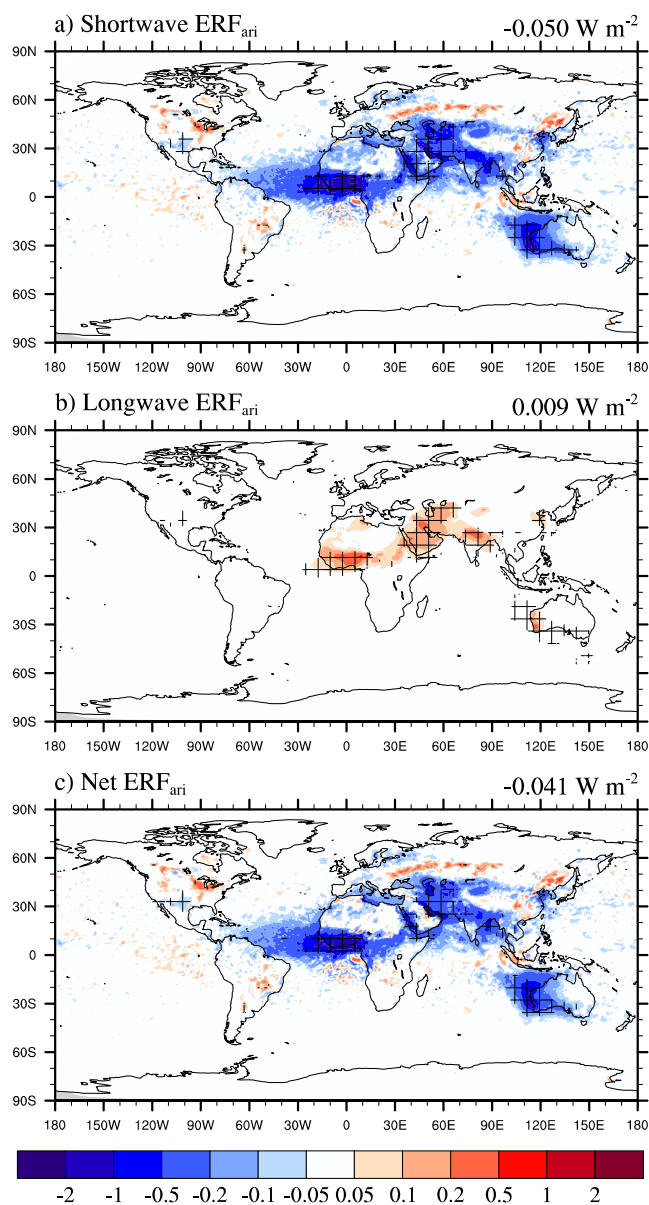

914

9

915 **Figure 7.** Spatial distribution of annual mean a) ND and b) AD emission fluxes in the PI  
 916 land cover condition. The differences of ND and AD emissions between PD and PI (PD  
 917 minus PI) land cover conditions are shown in panel c) and d), respectively. Panel e) is  
 918 the percentage fraction of crop PFT on each grid cell in PI. Results from NEW\_PI and  
 919 NEW are used for the PI and PD land cover conditions, respectively.

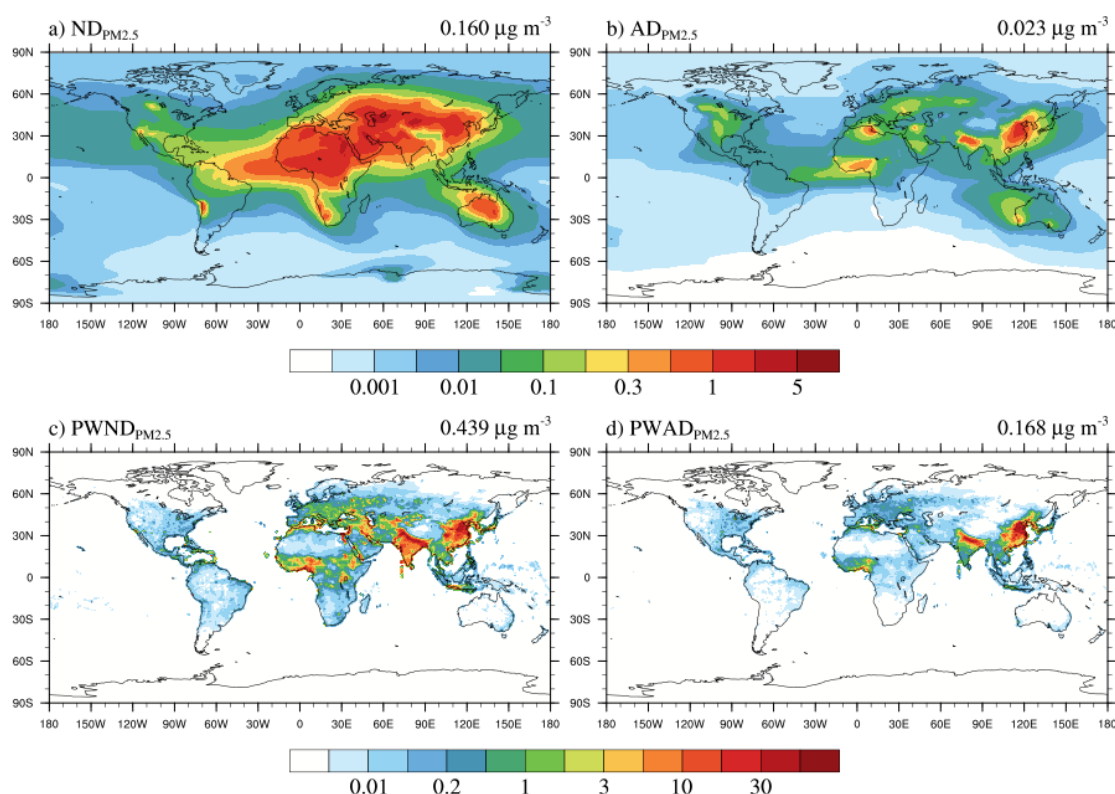

920

92

922 **Figure 8.** Spatial distribution of annual mean all-sky TOA a) shortwave, b) longwave,  
 923 and c) net  $ERF_{ari}$  of dust due to the land cover change from PI to PD. Hatching indicates  
 924 regions where the changes are significant to the 0.05 levels.

925

926

927 **Figure 9.** Global distribution of a) ND ( $ND_{PM2.5}$ ) and b) AD ( $AD_{PM2.5}$ ) surface mass  
 928 concentrations in the  $PM2.5$  size range. Panel c) and d) are the population weighted  
 929 surface mass concentrations for ND ( $PWND_{PM2.5}$ ) and AD ( $PWAD_{PM2.5}$ ). Results from  
 930 the NEW experiment are used in this figure.  $PWAD_{PM2.5}$  ( $PWND_{PM2.5}$ ) is determined  
 931 through multiplying the surface mass concentration of AD (ND) in the  $PM2.5$  size range  
 932 at each grid cell with a population weight factor, which is equal to the population density  
 933 at that grid cell divided by globally averaged population density. The population density  
 934 data used here is the data for year 2010 from the Gridded Population of the World,  
 935 Version 4 dataset (SEDAC, 2022). The resolution of this dataset is  $1^\circ$ , which is  
 936 compatible with the horizontal resolution of our model grid.
