12 **Key points:**

13 • Dip slip along curved ring faults at volcanoes generates $M_w > 5$ earthquakes dominated by a

14   compensated-linear-vector-dipole component.

15 • We propose a method for estimating ring-fault parameters by moment tensor inversion using long-period

16   seismic data.

17 • Our estimation of ring-fault parameters of earthquakes at the Sierra Negra caldera yields results consistent

18 with geodetic observations.

19 **Abstract**

20   Moderate earthquakes ($M_w > 5$) with moment tensors (MTs) dominated by a vertical

21   compensated-linear-vector-dipole (vertical-CLVD) component are often generated by dip slip along a

22   curved ring-fault system at active volcanoes. However, relating their MTs to ring-fault parameters has been

23   proved difficult. The objective of this study is to find a robust way of estimating some ring-fault parameters

24   based on their MT solutions obtained from long-period seismic records. We first model the MTs of

25   idealized ring-faulting and show that MT components representing the vertical-CLVD and vertical

26   strike-slip mechanisms are resolvable by the deviatoric MT inversion using long-period seismic waves,

27   whereas a component representing the vertical dip-slip mechanism is indeterminate owing to a shallow

28   source depth. We then propose a new method for estimating the arc angle and orientation of ring-faulting

29   using the two resolvable MT components. For validation, we study a vertical-CLVD earthquake that

30   occurred during the 2005 volcanic activity at the Sierra Negra caldera, Galápagos Islands. The resolvable

31   MT components are stably determined with long-period seismic waves, and our estimation of the ring-fault

32   parameters is consistent with the ring-fault geometry identified by previous geodetic studies and field

33   surveys. We also estimate ring-fault parameters of two earthquakes that took place during the 2018 activity

34   at the caldera, revealing significant differences between the two earthquakes in terms of slip direction and

35   location. These results show the usefulness of our method for estimating ring-fault parameters, enabling us

36   to examine the kinematics and structures below active volcanoes with ring faults that are distributed

37   globally.

1 Introduction

Seismological methods can be used for the study of active volcanoes to investigate geometries of subsurface structures and the physics of fluid transport into the magma plumbing system. Observations and analyses of shallow earthquakes with volcanic origins provide information on stress levels in volcanic edifices caused by magmatic pressures ascending from depth. This information is important for predicting eruptions and assessing hazards related to volcanic activity (e.g., McNutt, 2002; Chouet, 2003; Kawakatsu and Yamamoto, 2015). In most cases, small earthquakes are analyzed with in situ or near-field observations to infer detailed dynamics of magma transport or brittle fractures of volcanoes; for example, Kilauea in Hawaii (e.g., Neal et al., 2019; Shelly and Thelen, 2019) or Bárdarbunga in Iceland (e.g., Gudmundsson et al., 2016; Parks et al., 2017). In contrast, moderate volcanic earthquakes are sometimes recorded by regional and global seismic networks (e.g., Kanamori and Given, 1982; Kanamori et al., 1984; Kanamori and Mori, 1992; Ekström, 1994; Shuler et al., 2013a). If seismic signals radiated by such earthquakes can be utilized, it is possible to study volcanoes distributed globally, including those on remote islands or underwater without local observation systems. These include submarine volcanoes near Torishima Island, south of Japan (e.g., Kanamori et al., 1993; Fukao et al., 2018; Sandanbata et al., 2018), and near Curtis Island, north of New Zealand (Gusman et al., 2020), which caused earthquakes with seismic magnitudes of > 5, and submarine volcanic areas near Mayotte Island in the Comoro Islands, which showed significant seismicity during 2018–2019 (Cesca et al., 2020; Darnet et al., 2020).

56   One of the most notable types of volcanic earthquake observed at regional or global scales are those

57   with seismic magnitudes of $M_w > 5$ that are characterized by deviatoric moment tensors (MTs) having a

58   dominant vertical compensated-linear-vector-dipole (vertical-CLVD) component (e.g., Frohlich, 1994;

59   Kanamori et al., 1993; Ekström, 1994; Shuler et al., 2013a; 2013b). There are two types of vertical-CLVD

60   earthquake: one contains a dominant tension axis (vertical-T CLVD earthquakes), and the other contains a

61   dominant pressure axis (vertical-P CLVD earthquakes) (e.g., Ekström, 1994; Shuler et al., 2013a) (Figure 1).

62   Vertical-CLVD earthquakes cannot be explained by shear rupture on a planar fault, indicating that their

63   anomalous mechanisms are associated with complex source structures or magmatic processes. For

64   vertical-CLVD earthquakes at volcanoes, several models have been proposed, including ring-faulting (e.g.,

65   Ekström, 1994), rapid water–magma interaction initiated by magma intrusion into shallow crust (Kanamori

66   et al., 1993), and opening or closing of a horizontal crack (e.g., Riel et al., 2015; Fukao et al., 2018).

67   Among the different proposed source models, the ring-faulting mechanism explains many features

68   of vertical-CLVD earthquakes (e.g., Ekström, 1994; Shuler et al., 2013a; 2013b). Ekström (1994) showed

69   that deviatoric MT analyses of long-period seismic signals radiated by pure dip slips on a curved ring fault

70   result in vertical-CLVD focal mechanisms. Shuler et al. (2013a, 2013b) surveyed vertical-CLVD

71   earthquakes near volcanoes from 1976 to 2009 and located their centroids within the top 10 km of the crust,

72   which is consistent with the formation process of ring faults during caldera collapse (e.g., Cole et al., 2005;

73   Acocella, 2007; Geyer and Martí, 2014). Shuler et al. (2013a) showed that most vertical-CLVD earthquakes

74   were temporally associated with activity at nearby volcanoes with caldera structures. Vertical-CLVD

75   earthquakes near Bárdarbunga in Iceland and Nyragongo in the Democratic Republic of the Congo have

76   also been attributed to slips on non-planar ring faults (e.g., Gudmundsson et al., 2016; Parks et al., 2017;

77   Nettles and Ekström, 1998; Shuler and Ekström, 2009). The recurrence of vertical-CLVD earthquakes at

78   two shield volcanoes showing pronounced surface deformation or micro-seismicity along well-documented

79   ring-fault structures has indicted their origins related to ring-faulting at the Rabaul caldera in Papua New

80   Guinea (e.g., McKee et al., 1984; Mori and McKee, 1987; Mori et al., 1989; Shuler et al., 2013b) and the

81   Sierra Negra caldera in the Galápagos Islands (e.g., Amelung et al., 2000; Yun et al., 2006; Yun, 2007;

82   Jónsson, 2009; Bell et al., 2021).

83   MT inversion using long-period seismic waves has been applied to study the sources of

84   vertical-CLVD earthquakes from far-field observations (e.g., Shuler et al., 2013b; Duputel and Rivera,

85   2019; Fontaine et al., 2019). Because of long-period properties, detailed 3D velocity structures of the

86   volcanic edifices are not required. MT solutions of ring-faulting are known to reflect the properties of

87   earthquake sources, such as the kinematics of a central block and the dip directions of a ring fault (Ekström,

88   1994). When the central block moves upward on the inward-dipping ring fault (Figure 1a), or downward on

89   the outward-dipping ring fault (Figure 1b), vertical-T CLVD earthquakes are produced; in contrast, if the

90   kinematics of the block are reversed, vertical-P CLVD earthquakes are produced (Figure 1c and d). Hence,

91   the polarity of the MT solutions (vertical-T or -P) helps to determine either the kinematics of the central

92   block (upward or downward) or the dip direction of the ring fault (inward or downward), once either of the

93   two is constrained from other observations such as crustal deformation or micro-seismicity (e.g., Shuler and

94   Ekström, 2009; Gudmundsson et al., 2016).

95   However, it has been proved challenging to relate MT solutions obtained from long-period seismic

96   waves directly to ring-fault parameters such as arc angle, dip angle, and the location of slip along the ring

97   fault. One of the reasons for the difficulty is that amplitudes of radiated long-period seismic waves are

98   reduced owing to partial cancellations of long-period seismic waves from different portions of a ring fault

99   (Ekström, 1994). Another reason is the instability of MT inversion for shallow earthquakes (e.g.,

100   Dziewonski et al., 1981; Kanamori and Given, 1981). Although Shuler et al. (2013b) related MT solutions

101   obtained from long-period seismic records to ring-fault parameters using the plunge of the tension or

102   pressure axis and a parameter representing the dominance of the non-double-couple component, their

103   estimations were not always consistent with those observed in nature or in analog models.

104   Contreras-Arratia and Neuberg (2020) showed that detailed ring-fault parameters can be recovered from

105   near-field seismic stations with good azimuth coverage. Once reliable relationships between ring-fault

106   parameters and MT solutions obtained from long-period seismic records are established, MT inversion will

107   be a more powerful tool to remotely study the kinematics and subsurface structures of active volcanoes

108   distributed globally that cause ring-faulting.

109   The objective of this study is to find a robust way of estimating ring-fault parameters using the MT

110   solutions of vertical-CLVD earthquakes. We first model theoretical MTs of idealized ring-faulting with

111   variable ring-fault parameters and decompose them into MT components. Although the MT component

112   representing the vertical dip-slip mechanism is difficult to determine with long-period seismic waves, we

113   show that the remaining MT components can be used to estimate some ring-fault parameters. To validate

114   the theoretical argument, we estimate the ring-fault parameters of vertical-CLVD earthquakes at the Sierra

115   Negra caldera by investigating their resolvable components of MT solutions determined with long-period

116   seismic waves and then compare the estimated parameters with those identified in previous studies using

117   geodetic observations and field surveys. We also discuss possible bias in MT inversion caused by a seismic

118   source with a volume change close to the ring-faulting.

119   **2 Analysis**

120   2.1 Modeling and decomposition of moment tensors of ring-faulting

121   In this section, we theoretically explore robust relationships between MTs and ring-fault parameters.

122   We consider ring-faulting along a uniformly inward-dipping fault system that traces the circumference of a

123   circle. We define several ring-fault parameters as follows (Figure 2). The ring-faulting has a dip angle δ

124   that is constant along the fault system. The arc angle Θ is the central angle that measures the ruptured

125   segment along the circumference. The ring-fault azimuth is defined by the azimuth (from the north) of the

126   vector $\overrightarrow{OM}$, where O is the center of the circle and M is the midpoint of the ruptured segment. The ring-fault

127   azimuth indicates the ring fault's location along the circumference. The ring-fault orientation is the

128   geometrical orientation, measured clockwise from the north, of the tangent to the circle at M, and is normal

129   to $\overrightarrow{OM}$. The ring-fault azimuth can vary from 0° to 360°, whereas the ring-fault orientation can vary only

130 from 0° to 180°.

131 Here we consider idealized ring-faulting for a vertical-T CLVD mechanism: a pure reverse slip of 1

132 m along a circular inward-dipping ring fault (5 km radius at the surface) that extends from the surface to a

133 depth of 2 km. We model the theoretical MT of ring-faulting in a similar way to Ekström (1994) and Shuler

134 et al. (2013b); we discretize the ring fault into planar rhomboidal subfaults with a central angle of 1° for

135 each, compute the MT of each subfault (Box 4.4 in Aki and Richards, 2002), and sum up the MTs of the

136 subfaults. A ring fault is smaller than the wavelength, and the typical source time duration of vertical-CLVD

137 earthquakes is ~10 s (Shuler et al., 2013b), which is shorter than the wave period of the long-period seismic

138 waves that we use; hence, we can ignore the rupture propagation along the ring fault and assume the

139 point-source approximation. While fixing the ring-fault azimuth as 0° (i.e., the midpoint on the north), we

140 vary two ring-fault parameters, that is, the dip angle δ ranging from 45° to 90°, and the arc angle Θ

141 ranging from 0° to 360°. Only vertical-T earthquakes are discussed here because MTs of vertical-P

142 earthquakes can be examined by changing the signs of the MTs.

143 The scalar moment of the theoretical MTs is computed by following the definition given by Silver

144 and Jordan (1982) and Dahlen and Tromp (1998):

145   $M_0 = \sqrt{\Sigma_{ij} M_{ij} M_{ij}/2},$ (1)

146 where M_{ij} are the *ij* elements of an MT in spherical coordinates (r, θ, and ϕ) representing up, south, and

147 east, respectively. The moment magnitude is computed as:

148 $\qquad$ $M_w = \frac{2}{3}(\log_{10} M_0 - 9.10).$ (2)

149 with M_0 being measured in N m (e.g., Kanamori, 1977; Hanks and Kanamori, 1979).

150 $\qquad$ We next decompose the theoretical MTs in a similar way to Kawakatsu (1996). For the

151 decomposition, we define three moment scales corresponding to isotropic (*ISO*), vertical-CLVD (*CLVD*),

152 and difference (*D*) components with the three diagonal elements (M_{rr}, $M_{\theta\theta}$, and $M_{\phi\phi}$):

153 $\qquad$ $M_{ISO} = \frac{1}{3}(M_{rr} + M_{\theta\theta} + M_{\phi\phi}),$ (3)

154 $\qquad$ $M_{CLVD} = \frac{1}{3}(2M_{rr} - M_{\theta\theta} - M_{\phi\phi}),$ (4)

155 and

156 $\qquad$ $M_D = \frac{1}{2}(M_{\theta\theta} - M_{\phi\phi}).$ (5)

157 Note that the MT of ring-faulting contains no isotropic component ($M_{ISO} = 0$). Hence, using the two

158 moment scales (M_{CLVD} and M_D) and the non-diagonal elements ($M_{r\theta}$, $M_{r\phi}$, and $M_{\theta\phi}$), the MT of

159 ring-faulting can be uniquely decomposed into three deviatoric MT components in the following form:

160 $\qquad$ $\boldsymbol{M} = \boldsymbol{M}_{CLVD} + \boldsymbol{M}_{SS} + \boldsymbol{M}_{DS},$ (6)

161 where

162 $\qquad$ $\boldsymbol{M}_{CLVD} = M_{CLVD} \begin{bmatrix} 1 & & \\ 0 & -0.5 & \\ 0 & 0 & -0.5 \end{bmatrix},$ (7)

163
$$M_{SS} = M_D + M_{\theta\phi} = M_D \begin{bmatrix} 0 & & \\ 0 & 1 & \\ 0 & 0 & -1 \end{bmatrix} + M_{\theta\phi} \begin{bmatrix} 0 & & \\ 0 & 0 & \\ 0 & 1 & 0 \end{bmatrix}, \quad (8)$$

164   and

165
$$M_{DS} = M_{r\theta} + M_{r\phi} = M_{r\theta} \begin{bmatrix} 0 & & \\ 1 & 0 & \\ 0 & 0 & 0 \end{bmatrix} + M_{r\phi} \begin{bmatrix} 0 & & \\ 0 & 0 & \\ 1 & 0 & 0 \end{bmatrix}. \quad (9)$$

166   Note that the moment scales (Equations 3–5) are scalars, whereas the MT components (Equations 7–9) are

167   tensors.

168   The three MT components M_{CLVD}, M_{SS}, and M_{DS} represent different source types, i.e., the

169   vertical-CLVD (*CLVD*), vertical strike-slip (*SS*), and vertical dip-slip (*DS*) mechanisms, respectively

170   (Figure 2b). The sign of M_{CLVD} in Equation (7) depends on the type of vertical-CLVD earthquake:

171    $M_{CLVD} > 0$ for vertical-T earthquakes, and $M_{CLVD} < 0$ for vertical-P earthquakes.

172   Using absolute values defined by $|M_{CLVD}|$, $M_{SS} = \sqrt{M_D^2 + M_{\theta\phi}^2}$, and $M_{DS} = \sqrt{M_{r\theta}^2 + M_{r\phi}^2}$, we

173   can quantify the ratios of the *CLVD*, *SS*, and *DS* components in the MT of ring-faulting as:

174
$$\frac{|M_i|}{|M_{CLVD}| + M_{SS} + M_{DS}} \times 100 \ [\%], \quad (10)$$

175   where *i* represents *CLVD*, *SS*, or *DS*.

176   Figures 2c and 2d show the theoretical MTs and components for reverse slips on ring faults with dip

177   angles of 60° and 75°, respectively, which have arc angles of 90°, 180°, 270°, and 360° (2nd–5th rows,

178 respectively). The ring-fault azimuths are 0°, and the ring-fault orientations are 90° (i.e., the midpoint of the

179 ring fault is located on the north along the circumference of the circle). For comparison, MTs of slip on

180 planar faults with the same dip angles that are parallel to the ring-fault orientation are shown (1st row).

181 Ring-faulting has a vertical-CLVD mechanism, as long-period seismic contributions from different

182 segments along the curved ring fault partially cancel out (Ekström, 1994). Because the azimuths of

183 principal axes of the two double-couple components, M_{SS} and M_{DS}, are determined by the strike angle of

184 a planar fault (1st row), the double-couple components from different portions of the ring fault cause the

185 geometric cancellation. In contrast, as the *CLVD* component, M_{CLVD}, of a planar fault does not change with

186 its strike angle, the component of the ring fault accumulates and becomes more dominant in the moment

187 tensor as the arc angle increases.

188 2.2 Indeterminate *DS* component at a shallow source depth

189   Once the MT solution of ring-faulting is determined, the ring-fault parameters, namely, dip angle,

190 arc angle, and ring-fault azimuth (Figure 2a), can be estimated from the ratios of the three MT components

191 and azimuths of the principal axes of the *SS* and *DS* components. However, the *DS* component of such

192 shallow earthquakes is indeterminate from long-period seismic waves, because the component near the

193 solid surface has little contribution to long-period seismic waves (e.g., Dziewonski et al., 1981; Kanamori

194 and Given, 1981). The indeterminacy of the *DS* component makes it difficult to estimate the dip angle and

195   seismic magnitude of ring-faulting from long-period seismic waves. In addition, we cannot determine the

196   ring-fault azimuth, which is reflected in the azimuth of the tension axis of the *DS* component.

197   To confirm the indeterminacy of the *DS* component at a shallow depth, we synthetize long-period

198   (0.005–0.0125 Hz) seismic waveforms, including all the relevant phases (e.g., P, S, and surface waves), at a

199   virtual station from five hypothetical sources representing elementary components, M_{CLVD}, M_D, $M_{\theta\phi}$,

200    $M_{r\theta}$, and $M_{r\phi}$. We assume the same scalar moment $M_0 = 1.0 \times 10^{18}$ N m (M_w 5.9) using Equation (1) for

201   the sources (Figure 3). Details of the numerical method are described in the caption of Figure 3. For a

202   source at 2.5 km depth in the crust, amplitudes of long-period seismic waves radiated from the *DS*

203   component ($M_{r\theta}$, $M_{r\phi}$) are much smaller than those from the *CLVD* component (M_{CLVD}) and the *SS*

204   component (M_D, $M_{\theta\phi}$) (Figure 3a). Because of the inefficient seismic excitation, estimation of the *DS*

205   component is unstable. Also, small errors in the depth of the source result in large uncertainties in the *DS*

206   components owing to large variations in the amplitudes of synthetic long-period seismic waves. If the

207   source is at 10.5 km depth, the *DS* component radiates larger seismic waves (Figure 3b).

208   2.3 Resolvable MTs of ring-faulting

209   Given the indeterminacy of the *DS* component, we propose a method for estimating two ring-fault

210   parameters using only the *CLVD* and *SS* components, which are resolvable with long-period seismic waves.

211   Here we define the resolvable MT (M_{res}) by:

212 $$\boldsymbol{M}_{res} = \boldsymbol{M}_{CLVD} + \boldsymbol{M}_{SS}. \qquad (11)$$

213 $\boldsymbol{M}_{res}$ for the idealized ring-faulting is shown in the 6th column in Figures 2c and 2d. Here, we introduce

214 two new dimensionless physical parameters extracted from $\boldsymbol{M}_{res}$, as follows. The first parameter, k_{CLVD},

215 is the ratio of $|M_{CLVD}|$ to $|M_{CLVD}| + M_{SS}$ of $\boldsymbol{M}_{res}$ defined by:

216 $$k_{CLVD} = \frac{|M_{CLVD}|}{|M_{CLVD}| + M_{SS}} \times 100 \ [\%], \qquad (12)$$

217 which we call the *CLVD ratio*. This parameter can be used to estimate the ring-fault arc angle Θ (Figure

218 4a). As Θ increases from 0° (i.e., a planar fault) to 180°, k_{CLVD} increases from 66.7% to 100%. From

219 $\Theta = 180°$, k_{CLVD} decreases to a local minimum of 90% at ~255°, and then increases to 100% at 360°.

220 k_{CLVD} reaches 100% when Θ is 180° or 360°, where the *SS* component vanishes. When the dip angle is

221 constant along the ring fault, the relationship between k_{CLVD} and Θ does not depend on the dip angle

222 because pure dip slip on a planar fault with any dip angle in all cases results in the same *CLVD*-to-*SS*

223 component ratio of 2:1 (top row in Figures 2c and 2d). Thus, we can use k_{CLVD} to estimate some values of

224 Θ even if the *DS* component is indeterminate.

225   The second parameter, ψ, is defined as follows. The resolvable moment tensor $\boldsymbol{M}_{res}$ discussed here

226 is expressed by three orthogonal dipoles. We use the orientation of the dipole with the smallest absolute

227 moment to estimate the orientation of the ring fault. As shown in Figures 2c and 2d (6th column), this dipole

228 determines the elongation direction of the nodal-line pattern of the mechanism diagrams of $\boldsymbol{M}_{res}$. It can

229 also be shown that this orientation is the same as the orientation of the Null (N) axis of the *best-fitting*

230   *double-couple moment tensor* (pp. 248–251 of Shearer, 2009) shown by thin curves on the mechanism

231   diagrams (6th column of Figures 2c and 2d). We refer to the dipole axis as the *N-axis* and denote its

232   orientation by ψ, which is measured from the north, eastward-reckoned positive, $0 \leq \psi < 180°$. Figures

233   4b and 4c show the relationships between the ring-fault orientation and the N-axis for vertical-T and

234   vertical-P CLVD earthquakes. The ring-fault orientation is parallel or perpendicular to the N-axis

235   depending on $\Theta < 180°$ or $\Theta > 180°$, respectively. Because ψ is independent of the dip angle, this

236   parameter can be used to estimate the ring-fault orientation without knowing the *DS* component. We note

237   that what can be estimated from ψ is not the ring-fault azimuth but the orientation (Figure 2a); we cannot

238   distinguish two different ring faults with the same arc angle but rotated by 180° to each other.

239   Thus, $\boldsymbol{M}_{res}$ for shallow ring-faulting is useful for estimating ring-fault parameters by using

240   k_{CLVD} and ψ together. If k_{CLVD} is less than ~90%, Θ can be uniquely determined by k_{CLVD}

241   because Θ is a single-valued function of k_{CLVD} (Figure 4a). In this case, the ring-fault orientation is

242   parallel to the N-axis (Figures 4b and 4c). In contrast, if k_{CLVD} is larger than ~90%, Θ cannot be

243   determined uniquely and three values of Θ are possible for a given k_{CLVD} (Figure 4a); there also remain

244   two possibilities for the ring-fault orientation, parallel or perpendicular to the N-axis, depending on Θ

245   (Figures 4b and 4c). When $\Theta = 180°$, the N-axis orientation is indeterminate (Figures 2c and 2d), and

246   the ring-fault orientation cannot be determined. When $\Theta = 360°$, the ring-fault orientation is irrelevant.

247   **3 Case study: Vertical-CLVD earthquakes at the Sierra Negra caldera, Galápagos Islands**

248   In the previous section, we showed that the resolvable MT, $\boldsymbol{M}_{res}$, which is composed of the *CLVD*

249   and *SS* components, of ring-faulting is useful for estimating the arc angle Θ and the orientation of the ring

250   fault. Here, we investigate the relationships for a vertical-CLVD earthquake that occurred at the Sierra

251   Negra caldera prior to the 2005 volcanic activity. We first test the stability of $\boldsymbol{M}_{res}$ obtained from MT

252   inversion using long-period seismic records at far field. Then, we analyze $\boldsymbol{M}_{res}$ to estimate the ring-fault

253   parameters and compare them with other observations. We also investigate two vertical-CLVD earthquakes

254   at the caldera during volcanic activity in 2018.

255   3.1 M_w 5.5 vertical-T CLVD earthquake prior to the 2005 eruption

256   The Sierra Negra is a shield volcano located at the southern end of Isabella Island, in the Galápagos

257   Islands (Figure 5a). A shallow 7 km × 10.5 km caldera structure is formed at the summit of the 1124-m-high

258   volcano (Figure 5b; Reynolds et al., 1995). On 22 October 2005, the Sierra Negra caldera started eruption

259   activity at ~23:30 in UTC (e.g., Global Volcanism Project, 2005; Geist et al., 2008). At 20:34 on the same

260   day, about 3 h before initiation of the eruption, a vertical-T CLVD earthquake with M_w 5.5 occurred

261   (Chadwick et al., 2006; Jónsson, 2009). Clear long-period seismic signals from this earthquake were

262   observed at far-field stations (black kines in Figure 6). Geodetic observations with Global Positioning

263   System (GPS) and Interferometric Synthetic Aperture Radar (InSAR) suggested reverse slip along a

264   sinuous fault system with an inward dip angle on the western to southern parts of the caldera caused by a

265   pressurized sill-like magma chamber; this fault-motion mechanism is termed *trapdoor faulting* (e.g.,

266   Amelung et al., 2000; Jónsson, 2009). The occurrence of ring-faulting was indicated by a fresh fault scarp

267   on the southwestern part of the caldera (black dotted and solid curves in Figure 5b) identified by Geist et al.

268   (2008), who conducted field surveys at the caldera after the 2005 eruption. The shallow sill-like magma

269   chamber estimated from geodetic data (Jónsson, 2009) suggests that the earthquake occurred in the top ~2

270   km of the crust. For this geometry at such a shallow depth, the indeterminacy of the *DS* component is an

271   issue. Thus, this is a good example for investigating how the MT solution of a vertical-CLVD earthquake

272   caused by ring-faulting is related to the geometry of the ring fault identified by geodetic studies and field

273   surveys.

274   3.2 Data & methods

275   We perform MT inversion for the M_w 5.5 vertical-T earthquake near the Sierra Negra caldera. We

276   use the W-phase code for the inversion, including filtering, data screening, and convolution of Green's

277   functions (Kanamori and Rivera, 2008; Hayes et al., 2009; Duputel et al., 2012). We use the normal mode

278   method (e.g., Takeuchi and Saito, 1972) to compute Green's functions for the 1-D Preliminary Reference

279   Earth Model (PREM; Dziewonski and Anderson, 1981), in the same way as we did for the synthetic test in

280   Section 2.2. Long-period seismic waves are extracted from synthetic and observed waveforms by applying

281   a one-pass and fourth-order Butterworth bandpass filter with corner frequencies at 0.005 and 0.0125 Hz.

282   The inversion time window is set to include P, S, and surface waves. We assume zero contribution by a

283   volume change to the long-period seismic waves by imposing the zero-trace constraint, $M_{rr} + M_{\theta\theta} +$

284     $M_{\phi\phi} = 0$. This means that the seismic waves are entirely attributed to ring-faulting. Possible bias caused by

285   a volume change is discussed later in Section 4.2.

286   We use long-period seismic records at far-field stations for the inversion. We download seismic

287   records at stations within 5°–60° of the epicentral distance from the Data Management Center of the

288   Incorporated Research Institutions for Seismology (IRIS). For data screening (i.e., to remove bad data with

289   glitch, or low signal-to-noise ratio), we conduct a trial MT inversion using a source placed at 2.5 km depth

290   in the crust (i.e., 5.5 km depth of PREM including a 3-km oceanic layer) just below the Sierra Negra caldera

291   (0.83°S, 91.14°W). We assume a half duration and a centroid time shift reported in the Global Centroid

292   Moment Tensor (GCMT) Catalog. As a result of the trial inversion, we remove clearly bad data yielding a

293   normalized root mean square (NRMS) misfit > 0.9; the NRMS is defined by $\rho_i = \sqrt{\|\boldsymbol{s}_i - \boldsymbol{d}_i\|^2/\|\boldsymbol{s}_i\|^2}$,

294   where $\boldsymbol{s}_i$ and $\boldsymbol{d}_i$ are synthetic and observed data in the inversion time window at the i-th station,

295   respectively, and $\|\boldsymbol{s}\|$ represents the L2 norm of data vector $\boldsymbol{s}$. The selected dataset is composed of 25

296   seismic records at stations for the epicentral distance range from 12.4° to 46.6° and has a good azimuthal

297   coverage (Figure 6). The stations are from different seismic networks: the Global Seismograph Network (II,

298   IU), Broadband Tomography Under Costa Rica and Nicaragua (YO, 2003–2006), GEOSCOPE (G), and the

299   United States National Seismic Network (US).

300   To examine the stability of the MT solutions, we repeat MT inversion while moving the centroid

301   location in a 3D space around the Sierra Negra caldera. By examining the variation in the MT solutions, we

302   can assess the sensitivity of the solutions to small variations in estimated centroid location. For MT

303   inversion in the 3D space, centroid locations are distributed on two planes: the x–y (longitude–latitude)

304   plane at a depth of 2.5 km in the crust (Figure 7a), and the x–z (longitude–depth) plane along a latitude of

305   0.83°S across the caldera (Figure 7b). The centroid location intervals are 0.1° in the horizontal direction and

306   2.0 km in the vertical direction. At each centroid location, we try the inversion with different values for the

307   half duration t_h of the source time function and the centroid time shift t_c, assuming $t_h = t_c$, and then

308   determine an optimal value by a grid search minimizing the waveform misfit. The waveform fit for the MT

309   solution is measured with a global version of the NRMS misfit, $\rho = \sqrt{\sum_i \|\boldsymbol{s}_i - \boldsymbol{d}_i\|^2 / \sum_i \|\boldsymbol{s}_i\|^2}$, where each

310   sum goes over the number of seismic records. Then, from the solution, we obtain $\boldsymbol{M}_{res}$ defined by

311   Equation (11). Strictly speaking, to estimate $\boldsymbol{M}_{res}$ exactly with the constraint of $M_{r\theta} = M_{r\phi} = 0$, we need

312   to perform three-element MT inversions with the three constraints, $M_{r\theta} = M_{r\phi} = 0$, and $M_{rr} + M_{\theta\theta} +$

313    $M_{\phi\phi} = 0$. However, to compare our solutions with the GCMT solutions which were obtained for the five

314   MT elements with the only constraint $M_{rr} + M_{\theta\theta} + M_{\phi\phi} = 0$, we here perform five-element MT

315   inversions only with the constraint $M_{rr} + M_{\theta\theta} + M_{\phi\phi} = 0$, and after the solution was obtained we set

316    $M_{r\theta} = M_{r\phi} = 0$. In Supporting Information, we compare $\boldsymbol{M}_{res}$ obtained with these two methods and

317   show that the results are very similar when the datasets are good.

318   3.3 Results

319   3.3.1 Indeterminate *DS* component and stability of the resolvable MT

320   Figure 7a shows the global NRMS values for the MT solutions at locations on the x–y plane at a

321   depth of 2.5 km in the crust. In the area around the Sierra Negra caldera (white rectangle in Figure 7a), the

322   NRMS values are small. Figure 7b shows the global NRMS values for the MT solutions on the x–z plane

323   along latitude 0.83°S (dashed line in Figure 7a). Similarly, small NRMS values are given by most MT

324   solutions in the top ~15 km of the crust. For example, the MT solution at the caldera (0.83°S, 91.14°W; red

325   circle in Figure 7a) at a depth of 2.5 km reproduces the observed records well with an NRMS value of 0.365

326   (Figure 6). From the MT solutions in the 3D space, 53 solutions at different centroid grids yield NRMS

327   values of ≤ 0.365, which we refer to as *acceptable solutions* hereafter.

328   Figure 7c shows the MT solutions on the x–y plane at a depth of 2.5 km in the area around the

329   caldera (white rectangle in Figure 7a), and Figure 7d shows the solutions on the x–z plane along a latitude

330   of 0.83°S (white dashed line in Figure 7a) in the top ~10 km of the crust. The solutions on the two planes

331   differ significantly depending on centroid locations in the 3D space, although they yield similar small

332   NRMS values. Notably, at shallower depths in the crust, estimated M_w values and ratios of the *DS*

333   component are larger (Figure 7d). For the 53 acceptable solutions, M_W values are distributed widely from

334   5.50 to 6.49 (Figure 8a), and the ratio of the *DS* component, computed with Equation (10), ranges from

335   44.8% to 97.7% (Figure 8b). These results demonstrate the instability of MT inversion caused by the

336   indeterminate *DS* component, as discussed in Section 2.2.

337   From the MT solutions at centroid locations on the x–y and x–z planes, we extract $\boldsymbol{M}_{res}$ defined by

338   Equation (11) (Figures 7e and 7f). $\boldsymbol{M}_{res}$ on the two planes have similar focal mechanisms and M_W. M_W

339   values of $\boldsymbol{M}_{res}$ are in a narrow range (5.33 ± 0.04) for the 53 acceptable solutions (Figure 8c). Also, $\boldsymbol{M}_{res}$

340   for the acceptable solutions contain stable values of the CLVD ratio k_{CLVD} ($73.0\% \pm 3.0\%$; Figure 8d) and

341   the N-axis azimuth ψ ($102.7° \pm 3.0°$; Figure 8e). These results confirm that $\boldsymbol{M}_{res}$ is stably obtained for

342   vertical-CLVD earthquakes, even in the cases where centroid locations are not accurately determined,

343   indicating its stability under the presence of noise in observed data. Thus, the two physical parameters (i.e.,

344   k_{CLVD} and ψ) obtained from $\boldsymbol{M}_{res}$ can be used to reliably estimate ring-fault parameters.

345   In Figure 9 and Table 1, we compare the MT solution obtained for the centroid location at a depth of

346   2.5 km just below the caldera ($0.83°$S, $91.14°$W) with the solution from the GCMT Catalog. The centroid

347   depth of the GCMT solution is 9.0 km in the crust (i.e., 12 km of PREM including a 3-km oceanic layer).

348   The two MT solutions, including the indeterminate *DS* component, have very different focal mechanisms,

349   M_W values, and ratios of the *DS* component (Figures 9a and 9b). In contrast, $\boldsymbol{M}_{res}$ extracted from the two

350   different solutions show similar values for M_w (5.31 and 5.31), k_{CLVD} (73.4% and 77.3%), and ψ (101.9°

351   and 96.3°; Figures 9c and 9d). These results demonstrate that $\boldsymbol{M}_{res}$ can be reliably estimated from various

352   available catalogs such as the GCMT, even if the centroid depth and the complete MT are not accurately

353   determined for the shallow earthquakes (e.g., Chu et al., 2009; Wimpenny and Watson, 2020).

354   3.3.2 Ring-fault parameters inferred from the resolvable MT

355   We next estimate ring-fault parameters for the 2005 vertical-T CLVD earthquake at the Sierra Negra

356   caldera from M_{res} of the MT solution (Figure 9c). If we assume that the seismic waves are generated

357   entirely from idealized ring-faulting (uniform slip along a circular ring fault with a constant dip angle),

358   M_{res} with a value of k_{CLVD} of 73.4% indicates a ring fault with an arc angle Θ of ~80° (Figure 4a). In

359   such a case of $\Theta < 180°$, the N-axis with ψ of 101.9° suggests that the ring-fault orientation is a direction

360   rotated slightly clockwise from the E–W direction. Similarly, the intra-caldera fault (black curve in Figure

361   5b), which was attributed to the earthquake source by geodetic observations and field surveys (Amelung et

362   al., 2000; Jónsson, 2009; Geist et al., 2008), has an arc angle a little smaller than 90° and its orientation is

363   slightly rotated clockwise from the E–W direction, if we approximate the fault as a circular arc. Although

364   here we do not consider complexities of the actual fault geometry and slip distributions, the overall

365   agreement of the ring-fault parameters with the well-documented intra-caldera fault geometry strongly

366   suggests that we can study geometries of ring faults at volcanoes by analyzing the M_{res} of MT solutions

367   obtained from long-period seismic records at far field.

368   3.4 Insights into two vertical-CLVD earthquakes prior to and during the 2018 eruption

369   The Sierra Negra caldera renewed its eruption activity at ~19:40 on 26 June 2018 (UTC), which

370   lasted until 23 August (Global Volcanism Program, 2018; Vasconez et al., 2018; Bell et al., 2021). The

371   activity included eruptions from several fissure vents along the northern part of the caldera rim and on the

372   northern side of the volcanic flank, and large surface deformation with increased seismicity along the

373   intra-caldera fault system (Bell et al., 2021). Prior to and during the eruption, two vertical-CLVD

374   earthquakes with $M_w > 5$ were reported near the Sierra Negra caldera: a vertical-T earthquake with M_w 5.3 at

375   9:15 on 26 June, about 10 h before the initiation of the eruption, and a vertical-P earthquake with M_w 5.1 at

376   0:30 on 5 July. Bell et al. (2021) analyzed GPS records at the caldera and attributed the two earthquakes to

377   trapdoor faulting events on the intra-caldera fault structure. This indicates the ring-faulting origin of the

378   earthquakes.

379   The difference in the types of vertical-CLVD earthquake (vertical-T or P) can be explained by

380   flipped kinematics of slips on inward-dipping ring faults. Bell et al. (2021) reported that the first

381   (vertical-T) earthquake took place during the inflation phase of the caldera, preceding the eruption, and

382   caused large uplift of the inner caldera floor; on the other hand, the second (vertical-P) earthquake occurred

383   during a rapid deflation phase after the initiation of the eruption and the caldera floor subsided. Shuler et al.

384   (2013a) demonstrated similar temporal relationships between vertical-CLVD earthquakes and an eruption

385   by global observations; in other words, vertical-T earthquakes were often observed before an eruption,

386   whereas most vertical-P earthquakes occurred after an eruption started. Considering the co-seismic

387   deformation patterns of the caldera, it is reasonable to attribute the vertical-T earthquake to upward motion

388   of the central block along an inward-dipping ring fault (Figure 1a), and the vertical-P earthquake to a drop

389   of the block slipping on an inward-dipping ring fault (Figure 1c).

390   To provide insights into the source geometries of two vertical-CLVD earthquakes, we here analyze

391   their MT solutions from the GCMT Catalog (Table 1, Figures 10a and 10c). Focal mechanisms and the

392   parameters (k_{CLVD} and ψ) of $\boldsymbol{M}_{res}$ extracted from the MT solutions of the vertical-T and P earthquakes

393   are shown in Figures 10b and 10d, respectively. For the vertical-T earthquake, k_{CLVD} is 72.2% and ψ is

394   86.4° (approximately E–W), and for the vertical-P earthquake, k_{CLVD} is 71.9% and ψ is 55.5°

395   (approximately NE–SW). The small values of k_{CLVD}, 72.2% for the vertical-T earthquake and 71.9% for

396   the vertical-P earthquake, indicate that both earthquakes occurred along short ring faults with arc angles Θ

397   of ~80°, according to the relationship between k_{CLVD} and Θ (Figure 4a). In contrast, the significant

398   difference in ψ of ~31° implies that the earthquakes occurred at different locations along the intra-caldera

399   fault system. Using the relationship between the N-axis of $\boldsymbol{M}_{res}$ and the orientation of the ring fault with

400    $\Theta < 180°$ (top row in Figure 4b), the N-axis of $\boldsymbol{M}_{res}$ is expected to be parallel to the ring-fault orientation.

401   Therefore, we estimate that the vertical-T earthquake occurred on a ring-fault segment oriented in the E–

402   W direction, whereas the vertical-P earthquake occurred on a different segment oriented in the NE–SW

403   direction. Given the fault structures exposed on the caldera floor (Figure 5b), we suggest that the vertical-T

404   earthquake was generated by reverse slip on the southern intra-caldera fault, which may partially

405   correspond to the fault estimated as generating the 2005 earthquake (the eastern part of black curve in

406   Figure 5b). By contrast, we infer that the vertical-P earthquake occurred on another ring-fault segment on

407   the southeastern or northwestern portion, although we cannot determine which of the two segments from

408    $\boldsymbol{M}_{res}$.

409   We compare our estimations with geodetic observations by Bell et al. (2021), who used GPS data

410   recorded on the caldera floor. The authors reported that the vertical-T earthquake caused large co-seismic

411   uplift of 1.8 m and 1.4 m at GPS stations GV09 and GV06, respectively (Figure 5b), which supports our

412   estimation of the vertical-T earthquake along the southern fault. On the other hand, the second earthquake

413   caused large subsidence of 71 cm at GV06, but only 15 cm at GV09. The larger displacement at GV06 than

414   GV09 supports that the main rupture of the vertical-P earthquake was on the southeastern part of the

415   intra-caldera fault, which is consistent with one of the two candidates that we estimate for the geometry of

416   the vertical-P earthquake (i.e., southeastern or northwestern intra-caldera fault). For reference, we indicate

417   the more plausible ring-fault geometry of the vertical-P earthquake by a gray dotted curve in Figure 5b.

418   Thus, we suggest that the clear differences between the parameters of $\boldsymbol{M}_{res}$ for the two vertical-CLVD

419   earthquakes offer information about significant differences in source locations along the intra-caldera fault

420   system.

421   **4 Discussion**

422   4.1 Efficiency of long-period seismic excitation from ring-faulting

423   As demonstrated above, the nature of seismic excitation from ring-faulting is very different from

424   that of regular tectonic earthquakes. In general, despite the spectacular surface expression of ring faults, the

425   seismic excitation, especially at long periods (greater than ~100 s), is inefficient, which often causes

426   difficulty in interpretation. We have already discussed several specific cases above, and here we add some

427   general discussion to clarify the problem with the inefficient seismic excitation.

428   There are two aspects to this problem. First, as previously discussed by Ekström (1994) and Shuler

429   et al. (2013b), the ring-fault geometry results in cancellation of the source strength, as measured by the

430   scalar moment. As discussed in Section 2, we represent the MT of ring-faulting by the sum of MTs of planar

431   rhomboidal subfaults under the point-source approximation. We then compute the scalar moment M_0 of

432   the ring-faulting using Equation (1). Figure 11a shows the ratio:

433         $$\frac{M_0}{\sum_i \Delta M_0^i} \qquad (13)$$

434   as a function of the dip and arc angles, where ΔM_0^i is the scalar moment of the i-th subfault along the ring

435   fault computed using Equation (1). This ratio is generally smaller than 1 owing to the geometrical

436   cancellation of the double-couple components (i.e., $\boldsymbol{M}_{SS}$ and $\boldsymbol{M}_{DS}$).

437   In addition to this geometrical cancellation, the efficiency of seismic excitation of ring-faulting is

438   reduced because of its shallow source property. As expressed by Equation (6), the MT of ring-faulting can

439   be expressed by the sum of three components, $\boldsymbol{M}_{CLVD}$, $\boldsymbol{M}_{SS}$, and $\boldsymbol{M}_{DS}$. Because of the very shallow depth,

440    $\boldsymbol{M}_{DS}$ does not contribute to long-period seismic excitation; by contrast, the other two components ($\boldsymbol{M}_{CLVD}$,

441    $\boldsymbol{M}_{SS}$), which we referred to as resolvable components, have contributions. The effect of little seismic

442   excitation from $\boldsymbol{M}_{DS}$ can be expressed by the following ratio of scalar moment of $\boldsymbol{M}_{res}$ to that of the

443   theoretical MT (Figure 11b):

444
$$\frac{M_0^{res}}{M_0},\qquad (14)$$

445   where M_0^{res} is the scalar moment based on Equation (1) for $\boldsymbol{M}_{res}$ (defined by Equation (11)).

446   Then, the combined effect can be given by the ratio (Figure 11c):

447
$$\frac{M_0}{\sum_i \Delta M_0^i} \times \frac{M_0^{res}}{M_0} = \frac{M_0^{res}}{\sum_i \Delta M_0^i}.\qquad (15)$$

448   As shown in Figure 11c, the excitation efficiency of long-period seismic waves from ring-faulting at a

449   shallow depth is generally low, being lower for ring faults dipping more steeply.

450   The inefficient excitation of long-period seismic waves explains many peculiar characteristics of

451   vertical-CLVD earthquakes. Ring-faulting may generate greater surface deformation than expected

452   empirically from their seismic magnitudes estimated with long-period seismic waves. This may explain that

453   the moment magnitude of the slip model geodetically estimated for an intra-caldera earthquake at the Sierra

454   Negra caldera was much larger than that determined with seismic data independently (Jónsson, 2009). If

455   vertical-T CLVD earthquakes at the submarine volcanoes near Torishima Island and Curtis Island are

456   related to ring-faulting, the disproportionately large tsunamis for their seismic magnitudes may be partially

457   a result of the inefficient seismic excitation. Kanamori et al. (1993) identified an azimuthally uniform

458   radiation pattern of Rayleigh waves and an absence of Love waves from a vertical-T earthquake. This

459   peculiarity can be explained by the inefficient excitation of the *DS* component, as well as the geometrical

460   cancellation of the double-couple components (Ekström 1994; Shuler et al., 2013b).

461   4.2 Effect of volume change on the zero-trace estimate of the *CLVD* component

462   In previous sections, we estimated the CLVD moment scale M_{CLVD} of ring-faulting, defined by

463   Equation (4), at a very shallow depth, with the assumption of a vanishing isotropic component M_{ISO},

464   defined by Equation (3). If a volume change occurs near ring-faulting, the estimated M_{CLVD} might be

465   biased. As the bias depends on the geometry of the magma reservoir, we discuss three cases below.

466   <u>Horizontal tensile crack</u>

467   The moment tensor for a horizontal tensile (or compressional) crack with a volume change ΔV is

468   given in the (r, θ, ϕ) coordinate system by (e.g., Kawakatsu and Yamamoto, 2015)

469    $$\boldsymbol{M}_{Tensile} = \Delta V \begin{bmatrix} \lambda + 2\mu & & \\ 0 & \lambda & \\ 0 & 0 & \lambda \end{bmatrix}. \quad (16)$$

470   As seismic excitation of a moment tensor $\boldsymbol{M}$ is determined by $(\boldsymbol{M}:\boldsymbol{\varepsilon})$, where $\boldsymbol{\varepsilon}$ is the strain tensor at the

471   source (Gilbert, 1971), the excitation by the horizontal tensile crack is proportional to $(\lambda + 2\mu)\varepsilon_{rr} +$

472    $\lambda\varepsilon_{\theta\theta} + \lambda\varepsilon_{\phi\phi}$, which is equal to σ_{rr}, where ε_{rr}, $\varepsilon_{\theta\theta}$, and $\varepsilon_{\phi\phi}$ are the rr, $\theta\theta$, and $\phi\phi$ elements of the

473   strain tensor, respectively, and σ_{rr} is the rr element of the stress tensor. For a very shallow source, $\sigma_{rr} \approx$

474   0. This means that a very shallow horizontal tensile crack has little seismic excitation (pp. 180–183 of

475   Dahlen and Tromp, 1998; Fukao et al., 2018).

476   Previous studies have suggested that the Sierra Negra caldera has a sill-like magma reservoir at a

477   depth of ~2 km (e.g., Amelung et al., 2000; Chadwick et al., 2006; Jónsson, 2009). Because a volume

478   change of such a shallow sill-like reservoir involves a moment tensor defined by Equation (16) and does not

479   contribute to long-period seismic waves, it is reasonable to attribute the seismic waves from the

480   vertical-CLVD earthquakes at the caldera only to ring-faulting, as done in Section 3.

481   The case for a horizontal tensile crack has an important implication for other types of volume

482   change. $\boldsymbol{M}_{Tensile}$ can be decomposed as:

$$\Delta V \begin{bmatrix} \lambda + 2\mu & & \\ 0 & \lambda & \\ 0 & 0 & \lambda \end{bmatrix} = \left(\lambda + \frac{2}{3}\mu\right)\Delta V \begin{bmatrix} 1 & & \\ 0 & 1 & \\ 0 & 0 & 1 \end{bmatrix} + \frac{4}{3}\mu\,\Delta V \begin{bmatrix} 1 & & \\ 0 & -0.5 & \\ 0 & 0 & -0.5 \end{bmatrix}. \qquad (17)$$

484   The first and second terms on the right-hand side represent isotropic and CLVD sources, respectively. Thus,

485   the vanishing excitation by a horizontal tensile crack simply means that a unit isotropic tensor $\begin{bmatrix} 1 & & \\ 0 & 1 & \\ 0 & 0 & 1 \end{bmatrix}$

486   is equivalent to a CLVD tensor $-\frac{4\mu}{3\lambda+2\mu}\begin{bmatrix} 1 & & \\ 0 & -0.5 & \\ 0 & 0 & -0.5 \end{bmatrix}$ for seismic excitation at a very shallow depth.

487   <u>Spherical source</u>

488   If the deformation below ring-faulting is represented by a spherical source given by a moment

489   tensor

$$\boldsymbol{M}_{Sphere} = \Delta V \begin{bmatrix} \lambda + \frac{2}{3}\mu & & \\ 0 & \lambda + \frac{2}{3}\mu & \\ 0 & 0 & \lambda + \frac{2}{3}\mu \end{bmatrix} = M_{ISO}^{Sphere}\begin{bmatrix} 1 & & \\ 0 & 1 & \\ 0 & 0 & 1 \end{bmatrix}, \quad (18)$$

491   where

492
$$M_{ISO}^{Sphere} = \left(\lambda + \frac{2}{3}\mu\right)\Delta V, \quad (19)$$

493   then, using the equivalence relation between the isotropic and CLVD tensors, the CLVD moment scale of

494   ring-faulting at a shallow depth is observed as a CLVD source with

495
$$M'_{CLVD} = M_{CLVD} - \frac{4\mu}{3\lambda+2\mu}M_{ISO}^{Sphere} = M_{CLVD} - \frac{4}{3}\mu\,\Delta V. \quad (20)$$

496   Thus, to estimate M_{CLVD} for ring-faulting, we need to add $\frac{4}{3}\mu\,\Delta V$ to the observed M'_{CLVD} estimated with

497   the assumption of $\Delta V = 0$.

498   <u>Vertical cylindrical source</u>

499   If the deformation below ring-faulting is represented by a vertical cylindrical source given by a

500   moment tensor

501
$$\boldsymbol{M}_{Cylinder} = \Delta V\begin{bmatrix}\lambda & & \\ 0 & \lambda+\mu & \\ 0 & 0 & \lambda+\mu\end{bmatrix} = \left(-\frac{2}{3}\mu\,\Delta V\right)\begin{bmatrix}1 & & \\ 0 & -0.5 & \\ 0 & 0 & -0.5\end{bmatrix} + \left(\lambda+\frac{2}{3}\mu\right)\Delta V\begin{bmatrix}1 & & \\ 0 & 1 & \\ 0 & 0 & 1\end{bmatrix}$$

502
$$= M_{CLVD}^{Cylinder}\begin{bmatrix}1 & & \\ 0 & -0.5 & \\ 0 & 0 & -0.5\end{bmatrix} + M_{ISO}^{Cylinder}\begin{bmatrix}1 & & \\ 0 & 1 & \\ 0 & 0 & 1\end{bmatrix}, \quad (21)$$

503   where

504
$$M_{CLVD}^{Cylinder} = -\frac{2}{3}\mu\,\Delta V \quad (22)$$

505   and

506
$$M_{ISO}^{Cylinder} = \left(\lambda + \frac{2}{3}\mu\right)\Delta V, \quad (23)$$

507   then, considering the additional isotropic and CLVD components from the vertical cylindrical source, the

508   CLVD moment scale of ring-faulting is equivalent to a CLVD source with

509
$$M'_{CLVD} = M_{CLVD} + \left(M_{CLVD}^{Cylinder} - \frac{4\mu}{3\lambda+2\mu}M_{ISO}^{Cylinder}\right)$$

510
$$= M_{CLVD} + \left\{-\frac{2}{3}\mu\,\Delta V - \frac{4\mu}{3\lambda+2\mu}\left(\lambda + \frac{2}{3}\mu\right)\Delta V\right\}$$

511
$$= M_{CLVD} - 2\mu\,\Delta V. \qquad (24)$$

512   Thus, we need to add $2\mu\,\Delta V$ to the observed M'_{CLVD} to estimate M_{CLVD} for ring-faulting.

513   To illustrate the equivalence relation between the isotropic and CLVD tensors discussed above, we

514   show synthetic long-period waveforms computed for a CLVD source, an isotropic source, and a horizontal

515   tensile crack source (Figure 12). For this comparison, we use a common metric for $\boldsymbol{M}_{CLVD}$, $\boldsymbol{M}_{ISO}$, and

516     $\boldsymbol{M}_{Tensile}$. If we use the definition of a scalar moment M_0, given by Equation (1), then a CLVD source,

517
$\begin{bmatrix} 1 & & \\ 0 & -0.5 & \\ 0 & 0 & -0.5 \end{bmatrix}$, an isotropic source, $\begin{bmatrix} 1 & & \\ 0 & 1 & \\ 0 & 0 & 1 \end{bmatrix}$, and a horizontal tensile crack source,

518
$\begin{bmatrix} \lambda + 2\mu & & \\ 0 & \lambda & \\ 0 & 0 & \lambda \end{bmatrix}$, can be written, respectively, as

519
$$M_0\begin{bmatrix} \sqrt{4/3} & & \\ 0 & -\sqrt{1/3} & \\ 0 & 0 & -\sqrt{1/3} \end{bmatrix}, \qquad (25)$$

520
$$M_0 \begin{bmatrix} \sqrt{2/3} & & \\ 0 & \sqrt{2/3} & \\ 0 & 0 & \sqrt{2/3} \end{bmatrix}, \qquad (26)$$

521   and

522
$$M_0 \sqrt{\frac{2}{(\lambda+2\mu)^2+2\lambda^2}} \begin{bmatrix} \lambda + 2\mu & & \\ 0 & \lambda & \\ 0 & 0 & \lambda \end{bmatrix}. \qquad (27)$$

523   Here, we use the same scalar moment of $M_0 = 1.0 \times 10^{18}$ Nm (M_w 5.9). The waveforms for the CLVD and

524   isotropic sources are quite similar to each other, except for the polarity and amplitude (Figures 12a and 12b).

525   Figure 12c shows waveforms for the horizontal tensile source. The amplitudes are very small, reflecting the

526   cancellation effects of $\boldsymbol{M}_{CLVD}$ and $\boldsymbol{M}_{ISO}$.

527   4.3 Limitations in analysis of long-period seismic waves from ring-faulting

528   We demonstrated the usefulness of MT inversion using long-period seismic waveforms for

529   studying slip kinematics and geometries of ring faults at active volcanoes. However, limitations in the use

530   of long-period seismic waves remain. Some moment tensor elements of ring-faulting are inefficient for

531   generating long-period seismic waves, so that parts of source parameters cannot be determined only with

532   the records. The temporal–spatial history of rupture propagation along a ring fault may not be resolved

533   owing to the long-period property. Additionally, our method assumes simple cases of ring-faulting, i.e.,

534   pure dip-slip motion along a circular fault geometry with uniform slip; however, ring-faulting can contain

535   slightly strike-slip motion, complex fault geometry, and nonuniform slip distribution. To recover such

536   detailed information of ring-faulting, shorter-period seismic waves may be utilized with heterogeneous 3-D

537   velocity structures around the calderas (e.g., Contreras-Arratia and Neuberg, 2019; Hejrani and Tkalčić,

538   2020). Also, recent studies demonstrated that inversion analysis using a simple 1-D Earth model can affect

539   the MT inversion results (Hjörleifsdóttir and Ekström, 2010; Hejrani et al., 2017); hence, effects of the 3-D

540   velocity structures on the resolvable moment tensors need to be further examined. It is also difficult to

541   constrain a source with a volume change that may accompany ring-faulting by using long-period seismic

542   waves alone. To constrain the mechanism of a source with a change in volume, geodetic observations of

543   surface deformation using such as GPS, tiltmeters, or InSAR are useful (e.g., Yun, 2007; Anderson et al.,

544   2019; Segall et al., 2019, 2020). Combinations of seismic analyses with geodetic observations will provide

545   more details about source processes of ring-faulting that involve volume change of a magma reservoir.

546   **5. Conclusions**

547   In this study, we investigated how source parameters of ring-faulting are related with MTs of

548   vertical-CLVD earthquakes determined with long-period seismic waves. Avoiding the indeterminate issue

549   of the vertical dip-slip component for shallow earthquakes, we proposed a new method to estimate the arc

550   angle and the orientation of the ring fault based on two physical parameters, namely, the CLVD ratio k_{CLVD}

551   and the N-axis azimuth ψ, of the resolvable MT $\boldsymbol{M}_{res}$, which is composed of the vertical-CLVD and

552   vertical strike-slip components. Through a case study of the 2005 vertical-CLVD earthquake at the Sierra

553   Negra caldera, we showed the stability of $\boldsymbol{M}_{res}$ obtained by MT inversion using long-period seismic

554 records at far field. We also demonstrated that the ring-fault parameters estimated with $\boldsymbol{M}_{res}$ were

555 consistent with the geometry of the ring fault identified by geodetic observations and field surveys. In

556 addition, we pointed out clear differences between $\boldsymbol{M}_{res}$ of two vertical-CLVD earthquakes during the

557 2018 activity at the caldera and suggested significant differences in the kinematics and source locations of

558 the two ring-faulting events. Analyses of long-period seismic waves from moderate vertical-CLVD

559 earthquakes observed globally allow remote estimation of ring-fault parameters at active volcanoes even

560 without local observation networks. A better understanding of ring-faulting will provide insights into

561 interactions of fault systems at volcanoes with magmatic processes, potentially leading to assessments of

562 volcanic hazards.

786   **Figures and tables**

787

788   **Figure 1 Two types of vertical-CLVD earthquake caused by ring-faulting.**

789   (a–d) The kinematics and geometry of ring-faulting corresponding to the two endmembers of

790   vertical-CLVD earthquakes (shown on the left). The circle represents the up-dip end of the ring fault,

791   with short lines indicating the dip direction to the down-dip end. The direction of motion of the central
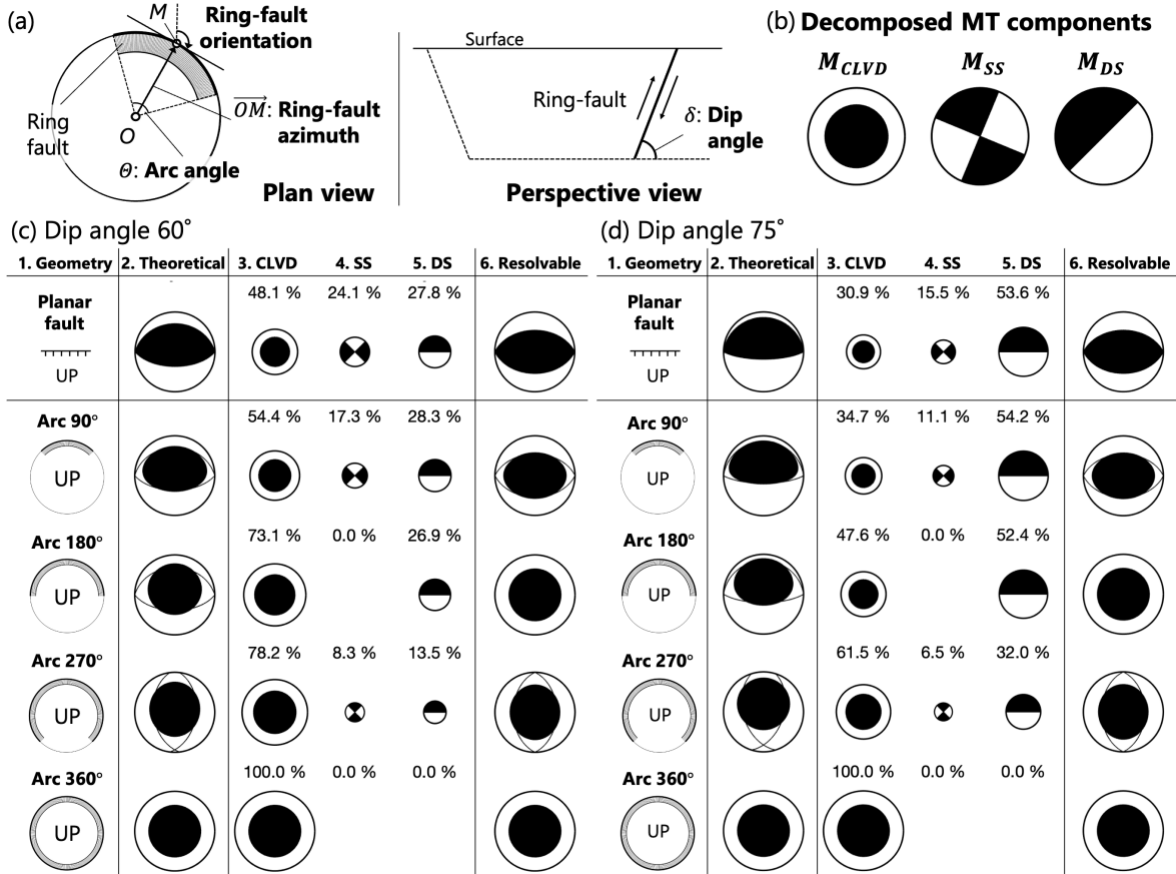

792   block is indicated at the center of the circle.

793

Figure 2 Modeling and decomposition of theoretical moment tensors of idealized ring-faulting.

(a) Ring-fault parameters. Thick and thin arc curves represent up-dip and down-dip ends, respectively.

Arc angle Θ, *dip angle δ*, and *ring-fault azimuth* $\overrightarrow{OM}$ are variable parameters. The *ring-fault*

orientation is perpendicular to the ring-fault azimuth. The dip angle is uniform along the ring fault. (b)

Three decomposed moment tensor (MT) components. (c–d) Theoretical MTs of ring-faulting with arc

angles of 90°, 180°, 270°, and 360° and with dip angles of (c) 60° and (d) 75°. For reference, an MT of

a planar faulting is also shown in the top row. Columns: (1) kinematics and geometry of ring-faulting,

(2–6) focal mechanism diagrams of (2) the theoretical MT, (3–5) decomposed MT components

803   (*CLVD*, *SS*, and *DS*) with their ratios, and (6) resolvable MT. The orientation of the *best double-couple*

804   *solution* is shown by thin curves in columns 2 and 6. All focal mechanisms are shown by projection of

805   the lower focal hemisphere. The diameter of the focal mechanism diagram is proportional to its scalar

806   moment but slightly exaggerated for the component with percentages of $< 10\%$ for clear visualization.

Figure 3 Synthetic long-period seismic waves from five elementary moment tensor components.

Synthetic long-period seismic waveforms from sources representing five elementary moment tensor

components. The centroid depth is (a) 2.5 km and (b) 10.5 km in the crust. M_D and $M_{\theta\phi}$ determine

the *SS* component, and $M_{r\theta}$ and $M_{r\phi}$ determine the *DS* component. The virtual station is located at

$(\varphi, \Delta) = (19.2°, 17.8°)$, where φ is the station azimuth from north (eastward positive), and Δ is the

813   distance from the source. We use the W-phase code (Kanamori and Rivera, 2008; Hayes et al., 2009;

814   Duputel et al., 2012) for the convolution of Green's functions and filtering. Green's functions are

815   computed by the normal mode method (e.g., Takeuchi and Saito, 1972), with the 1-D Preliminary

816   Reference Earth Model (PREM; Dziewonski and Anderson, 1981). A one-pass and fourth-order

817   Butterworth bandpass filter with corner frequencies of 0.005 and 0.0125 Hz is applied.

818

Figure 4 Relationship between M_{res} and ring-fault parameters.

(a) The CLVD ratio, k_{CLVD}, of the resolvable MT, $\boldsymbol{M}_{res}$, as a function of arc angle $\varTheta$. Note that the

relationship between k_{CLVD} and $\varTheta$ is independent of the dip angle of the ring fault. (b–c)

Relationship between ring-fault geometry and $\boldsymbol{M}_{res}$ for (b) vertical-T earthquakes and (c) vertical-P

earthquakes. In the 2nd column, the dip direction of the ring fault (inward or outward), the kinematics

824   of the central block (up or down), and the ring-fault orientation (an arrow) are shown. In the 3rd

825   column, M_{res} is shown with the orientation of its *N-axis* (arrow). In the 4th column, the *SS*

826   component is shown with its T- or P-axis (arrow). Note that the N-axis of M_{res} is the same as the T-

827   and P-axes of the *SS* component for vertical-T and vertical-P earthquakes, respectively.

Figure 5 Maps of the Galápagos Islands and the Sierra Negra caldera.

(a) Map of the Galápagos Islands. Topographic and bathymetric data is from GEBCO_2020. The

black rectangle in the inset panel indicates the area shown in (a). The black cross represents the

centroid location of the vertical-T earthquake of 22 October 2005 reported in the GCMT Catalog. (b)

Map of the Sierra Negra caldera. Topographic data is from the Advance Land Observation Satellite

(ALOS) World 3D–30 m DEM (AW3D30) provided by the Japan Aerospace Exploration Agency

(JAXA) (e.g., Tadono et al., 2014). The black curve indicates the fresh vertical scarp identified by

Geist et al. (2008) during a field survey in June 2006; the part represented by the solid curve was

clearly identified, whereas those along the dotted curves were less clearly defined. The red circles

represent locations of GPS stations used by Bell et al. (2021). The gray dotted curve indicates a

possible geometry inferred in this study for the 2018 vertical-P earthquake (see text in Section 3.4).
840

Figure 6 Model performance of MT inversion for the M_w 5.5 vertical-T CLVD earthquake of 22

October 2005.

Red and black lines represent synthetic and observed waveforms, respectively. The start and end

points of the inversion time window are indicated by red circles. In each inset map, the blue star and

the large red circle represent locations of the epicenter (0.83°S, 91.14°W) and the station. The station

azimuth (φ) and epicentral distance (Δ) are indicated at the top of each panel.

847

**Figure 7 MT inversion for the vertical-T CLVD earthquake of 22 October 2005 at the Sierra Negra**

849   **caldera.**

850   (a–b) Global NRMS misfits ρ of MT solutions at source locations distributed on (a) the x–y plane at a

851   depth of 2.5 km in the crust and (b) the x–z plane along a latitude of 0.83° (dashed white line in (a)).

852   The red circle in (a) and the red line in (b) represent the approximate locations of the Sierra Negra

853   caldera. (c–d) MT solutions at different centroid locations on (c) the x–y plane around the caldera (in

854   the area shown by the white rectangle in (a)) and (d) the x–z plane. (e–f) Resolvable MTs on (e) the x–

855   y plane around the caldera and (f) the x–z plane. All focal mechanisms are shown by projection of the

856   lower focal hemisphere. In (b), (d), and (f), the vertical axis represents the centroid depth in the crust.
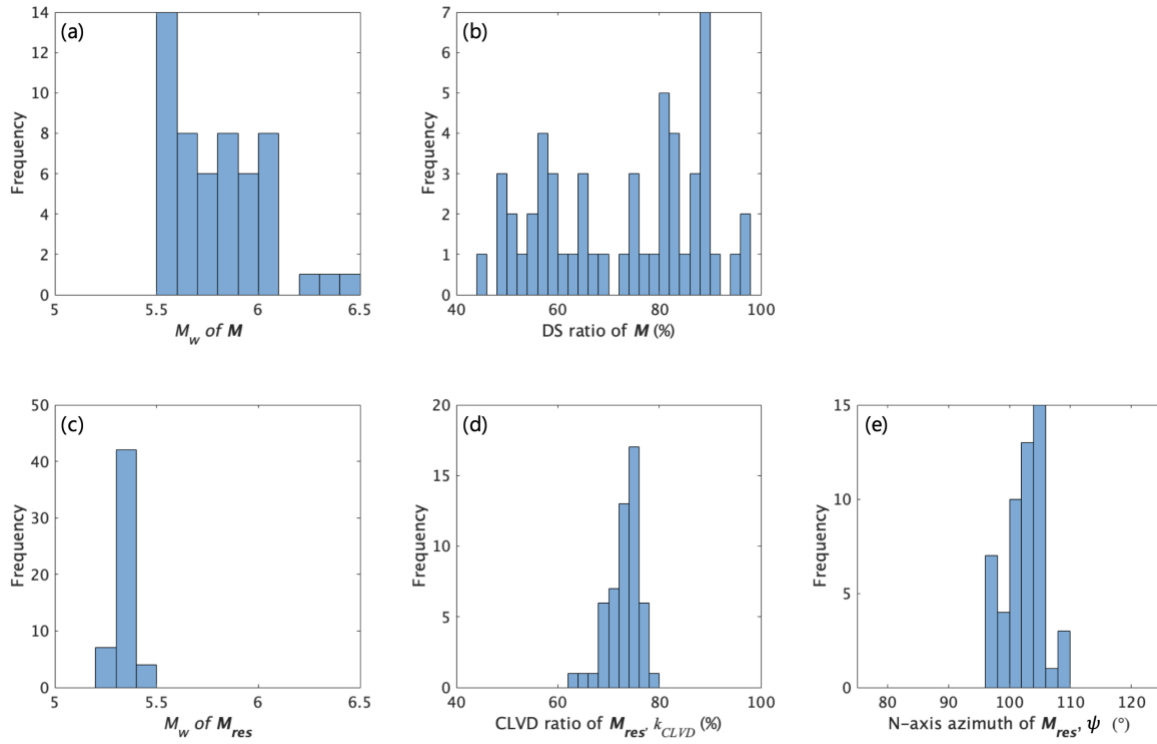

857

858   **Figure 8 Histogram of the parameters of acceptable MT solutions.**

859   (a) M_w and (b) the ratio of the *DS* component of the acceptable MT solutions. (c) M_w, (d) the CLVD

860   ratio k_{CLVD}, and (e) the N-axis azimuth ψ of $\boldsymbol{M}_{res}$ extracted from the acceptable MT solutions.
